BACKGROUND: Rectovaginal fistula (RVF) is a serious complication after colorectal anastomosis using a double-stapling technique. RVF following this procedure has been considered to be refractory to conservative treatment.

CASE PRESENTATION: A 75-year-old woman who underwent laparoscopy-assisted low anterior resection for early rectal cancer developed RVF on the 12th postoperative day. Conservative treatment was chosen and was successful. She was discharged from the hospital after 3 weeks with a normal oral diet.

CONCLUSION: Conservative treatment may be effective for RVF after colorectal anastomosis using a double-stapling technique when there is no evidence of defecation through the vagina.

1. Introduction

Colorectal anastomosis using a double-stapling technique has become a common procedure in low anterior resection for rectal cancer [1,2]. Rectovaginal fistula (RVF) is a serious complication of this method, with reported incidence of 1.6%–9.9% [3–6]. Management of RVF is difficult and conservative treatment has been considered to be ineffective [7,8]. Fecal diversion is generally recommended as the initial step to facilitate resolution of acute inflammation and associated infection [8], while additional surgical procedures, such as closure of the fistula or muscle flap repair, often are required, though outcomes are not always satisfactory [9–12]. Thus far, successful conservative treatment has been reported in only one case of a pinhole fistula [13].

Here, we report a case of a relatively large RVF after low anterior resection for rectal cancer using a double-stapling technique, in which conservative treatment was successful. This work has been reported in line with the SCARE criteria [14].

2. Case report

A 75-year-old woman was admitted to our hospital with bloody feces, and was diagnosed as having rectal cancer by colonoscopy. She had no particular past history, no family history, or no medication. A quarter-circular, type 1 tumor was found on the anterior wall of the lower rectum, with its lower edge approximately 6 cm from the anal verge. Laparoscopy-assisted low anterior resection with D3 lymph node dissection was performed. Intraoperatively, bleeding from the posterior wall of the vagina was insisted, with total blood loss of 630 g. After total mesorectal excision, the rectal stump was closed at 2 cm below the cancer using two 45-mm cartridges of a linear stapler. Anastomosis was performed with a circular stapler using a double-stapling technique. Pathologic stage was confirmed to be pT1b (SM, 4.5 mm), pN0, pPM0 (150 mm), pDM0 (5 mm), pStage I.

Oral diet was started on the third postoperative day, and discharge from the hospital was planned for the 12th postoperative day. However, massive fresh bleeding from the anus and vagina was observed on the day of discharge. Computed tomography showed air and coagulum in the vagina and no air in the peritoneal cavity (Fig. 1A). Enema using amidotrizoate sodium meglumine confirmed RVF formation (Fig. 1B). Colonoscopy showed the anastomosis at 4 cm from the anal verge and RVF formation between the anterior wall of the anastomotic ring and the posterior wall of the...
vagina. The diameter of the fistula was over 1 cm, and a thin scope (10.2 mm in diameter) could pass through it (Fig. 2A). Gynecologists examined the vagina and confirmed the fistula was located on the posterior to right wall of the upper vagina. Retrospective inspection of our operative video revealed that the linear stapler might have slightly included the vaginal wall (Fig. 3).

We chose conservative treatment because the bleeding stopped and vital signs were stable. Oral intake was stopped and total parenteral nutrition was started on the same day. Freeze-dried coagulation factor XIII (FXIII), derived from human plasma, was administered for 5 days (1440 U/day) because FXIII activity decreased to 66%. Oral intake was restarted on the 20th postoperative day after we confirmed by colonoscopy that the RVF decreased in size (Fig. 2B). Magnesium oxide and antiflatulent were administered so that soft defecation was observed 2 or 3 times a day. We judged that she could be discharged from the hospital on the 34th postoperative day because no fever or inflammatory response was observed, and there was no evidence of defecation from the vagina. Colonoscopy on the 50th postoperative day showed that the RVF was closed (Fig. 2C). No recurrence has been observed for 4 months.
3. Discussion

Low anterior resection with anastomosis using a double-stapling technique for rectal cancer is widely performed. Recently, advances in laparoscopic techniques have made it possible to apply a double-stapling technique even for very low rectal anastomosis. As for etiology, RVF has been thought to arise from inclusion of the vagina in the stapled anastomosis, spontaneous drainage of a pelvic abscess through the vagina, or injury of the vagina by the “dog ear” of the rectal stump [7]. In our case, the linear stapler might have slightly included the vaginal wall and we infer that the circular stapler might have punched just the edge of the included vaginal wall, and the point of intersection of the staples might have popped out on the 12th postoperative day, resulting in the sudden bleeding and RVF formation.

RVF following anastomosis using a double-stapling technique has been considered to be refractory to conservative treatment [3–8]. Thus, various surgical procedures, such as transvaginal or transanal resection or closure of the fistula, repair with a gracilis muscle flap, and diverting stoma for local preservation, have been reported [9–11].

In our case, the RVF closed without any surgical procedure, even though it was so large a thin scope could pass through it. There may be several reasons for this successful conservative treatment. First, there was no evidence of defecation through the vagina throughout the course. Second, good nutritional status was maintained because total parenteral nutrition was started immediately and the fasting period was only 8 days. Administration of FXIII also might have helped to heal the fistula. FXIII is a transglutaminase that is the last step in the coagulation cascade, which plays an important role in wound healing by stabilizing the fibrin clot [15]. Thus, administration of FXIII might accelerate wound healing by increasing circulating growth factors [16].

Although RVF following anastomosis using a double-stapling technique has been thought to be refractory to conservative treatment, our case may indicate that conservative treatment can be attempted when there is no evidence of defecation through the vagina.

Conflicts of interest

The authors declare that they have no competing interests.

Funding

None.

Ethical approval

Treatments for the patient were in accordance with the ethical standards of the responsible committees on human experimentation (institution and national).

Consent

Written informed consent to publish was obtained from the patient.

Author contribution

SE, SY and MI carried out the diagnosis of the tumor, and carried out the surgery of this patient. SE, SY, KO, TN, KM, HS, YT, AH, HS and MI participated in the patient’s care. SE and NA participated in writing and revising the manuscript critically. All authors read and approved the final manuscript.

Guarantor

Shigenobu Emoto and Toshiaki Watanabe.
