ABSTRACT

Small air pressure fluctuations in the atmosphere are responsible for the pressure pumping effect, which leads to an enhancement of soil gas transport. To investigate the spatial variability of these air pressure fluctuations, several high-precision differential pressure sensors were installed at the floor of a Scots pine forest. The alignment of the pressure sensors allowed for the determination of the propagation direction and speed of the observed air pressure fluctuations. Below-canopy and above-canopy airflow characteristics were monitored to find possible links between the air pressure fluctuations and the airflow. Results show that the propagation direction of the air pressure fluctuations observed at the forest floor correspond to the above-canopy and not to the below-canopy wind direction. Moreover, propagation speed of the air pressure fluctuations is higher than the below-canopy wind speed and corresponds to above-canopy wind speed. These findings indicate a connection between below-canopy air pressure fluctuations and above-canopy airflow. The air pressure fluctuations were found to be well correlated up to a distance of 15 m. With increasing distance, the correlation strongly decreases. However, the calculated pressure pumping coefficient, which quantifies the strength of the pressure pumping effect, yields similar values up to a distance of 90 m. This allowed specifying the range of influence of the air pressure fluctuations.

Keywords: air pressure fluctuations, pressure pumping, soil gas transport, Scots pine (Pinus sylvestris L.)

1. Introduction

Gas fluxes between the soil and the atmosphere are highly relevant for the climate of the Earth (Ball, 2013). Large amounts of carbon dioxide, methane and nitrous oxide are emitted from the soil into the atmosphere (Smith et al., 2003; Vor et al., 2003). One factor governing the emission of greenhouse gases into the atmosphere is the soil gas transport. Commonly, it is assumed that soil gas transport is dominated by molecular diffusion (Maier and Schack-Kirchner, 2014). However, soil gas transport can also be altered through advection (Amos et al., 2009; Bowling and Massman, 2011). In addition, an enhancement of soil gas transport was observed during periods of high wind speed. This enhancement results from an advective–dispersive enhancement of soil gas transport in the soil pores through dynamic changes in the air pressure field above the soil and is referred to as wind-induced pressure pumping effect (Massman et al., 1997; Poulsen and Sharma, 2011; Maier et al., 2012). Well and deeply aerated soils are believed to be most susceptible to the pressure pumping effect (Maier et al., 2010, 2012).

Recent research at a conifer forest site showed that wind-induced air pressure fluctuations in a specific frequency range influence the topsoil gas transport (Mohr et al., 2016). Moreover, a pressure pumping coefficient (PPC, in Pa s$^{-1}$) was derived, describing the strength of the pressure pumping. Based on 30 min intervals, a connection between PPC and the above-canopy wind speed was found. It was assumed that the observed air pressure fluctuations originate from air masses above the canopy, which would lead to time differences between signals measured at different heights. However, in their study no time lags between the air pressure signals at different heights were observed, leaving the origin of the air pressure fluctuations unclear. Thus, this study aims to find possible links between airflow characteristics and wind-induced air pressure fluctuations at the forest site, to investigate their spatial below-canopy variability and to describe the characteristics of pressure waves associated with air pressure fluctuations. Furthermore, it aims to determine the spatial variability of the pressure pumping effect.

2. Materials and methods

2.1. Measurement site

Airflow and air pressure measurements were conducted from 4 October 2016 to 24 November 2016 at the forest meteorological
research site in Hartheim, Germany, located approximately 25 km to the south-west of Freiburg (47°56′N, 7°36′E). The forest at the research site is a single-layered plantation of Scots pine (*Pinus sylvestris* L.) with a mean tree height *h* of 18 m, a mean stand density of 580 trees ha⁻¹ and a mean plant area index of 1.5. The soil at the research site is well-aerated and classified as Haplic Regosol after the world reference base for soil resources classification (FAO, 2015).

### 2.2. Airflow measurements

Airflow at the research site was monitored by measuring the *x*-(*u*), *y*-(*v*), and *z*-(*w*) component of the wind vector (in m s⁻¹) with ultrasonic anemometers (81000VRE, R.M. Young Company, Traverse City, MI, USA). Two measurement towers (T1, T2) separated by a distance of 40 m were used for the airflow measurements: T1 with a height of 30 m and T2 with a height of 18 m. The airflow measurement heights were 2 m (*z*/2*h*), 9 m (*z*/2*h*), 18 m (*z*/2*h*), 21 m (*z*/2*h*) and 30 m (*z*/2*h*) at T1 and 18 m (*z*/2*h*) at T2. The airflow data were recorded at a frequency of 10 Hz.

### 2.3. Air pressure measurements

Piezo-resistive differential pressure sensors (GMSD 2.5 MR, Greisinger Electronic GmbH, Regenstauf, Germany) with a reference box were used for the air pressure measurements (Mohr et al., 2016). This system allows for measuring all air pressure fluctuations with frequencies >0.0005 Hz. Two measurement configurations were set up at the forest floor: Five pressure sensors (N, E, S, W, C) were aligned in an array between the two towers (Fig. 1a). The air pressure *p* (in Pa) measured halfway between the two towers was considered as the reference pressure *p_C* measured at the center C of the sensor array. In addition, air pressure in a distance *x* = 15 m from C to the north (*p_N*), east (*p_E*), south (*p_S*) and west (*p_W*) was measured.

Two pressure sensors were used to evaluate the spatial variability of air pressure fluctuations, the distance *d_i* (*i* = 1, …, 5) between the two sensors was gradually decreased from around 90 m to around 10 m (Fig. 1b).

The sampling frequency of air pressure was 2 Hz.

### 2.4. Data processing

Data analysis was based on 30 min intervals. Relevant air pressure fluctuations were found to occur when mean above-canopy wind speed exceeds 1 m s⁻¹, which is consistent with results from a previous study (Mohr et al., 2016). Therefore, all 30 min intervals with mean above-canopy wind speed lower than 1 m s⁻¹ were excluded from further analysis.

#### 2.4.1. Air pressure data

All measured air pressure signals were filtered with a fourth order infinite impulse response band pass filter with lower and upper cutoff-frequencies of 0.01 Hz and 0.10 Hz. This frequency range was shown to be relevant for wind-induced pressure pumping (Mohr et al., 2016).

For the determination of the spatial variability of air pressure fluctuations, the cross-correlation function *xcf* was calculated between the filtered air pressure signals of two pressure sensors. The maximum value of *xcf* (\(\text{xcf}_{\text{max}}\)) was used to specify the strength of cross-correlation between the two pressure signals.

Results reported by Mohr et al. (2016) demonstrate simultaneous occurrence of air pressure fluctuations at *z*/3*h* to *z*/5*h*. In contrast, results from trial experiments using transects of air pressure sensors at the forest floor showed the same air pressure fluctuations at *z*/2*h* to *z*/3*h*.
pressure fluctuations, but with clear time lags. Thus, it was inferred that the observed air pressure fluctuations propagate horizontally as a plane wave rather than vertically.

To determine the direction of propagation of the air pressure fluctuations, the time differences between \( p_C \) and \( p_N \), \( p_W \), and \( p_S \) (\( \Delta t_N \), \( \Delta t_S \), \( \Delta t_E \), and \( \Delta t_W \)) were used. The time differences were specified using \( \Delta t \). The order of observation of the air pressure fluctuations at each pressure sensor results from these time differences. Eight different orders are possible:

- Air pressure fluctuations propagating from northeastern (NE) to southwestern (SW) directions: NECWS and ENCSW.
- Air pressure fluctuations propagating from southeastern (SE) to northwestern (NW) directions: SECWN and ESNW.
- Air pressure fluctuations propagating from southwestern (SW) to northeastern (NE) directions: SWCEN and WSCNE.
- Air pressure fluctuations propagating from northwestern (NW) to southeastern (SE) directions: NWCES and WNCSE.

Assuming a plane air pressure wave propagating from SE to NW, where the wave front is perpendicular to the direction of propagation, four different right-angled triangles can be used to calculate the angle of incidence (\( \alpha \), in \(^\circ\)) and angle of emergence (\( \beta \), in \(^\circ\)) at C (cf. Fig. 1a). For both angles \( N \) is defined as \( 0^\circ/360^\circ \), E as \( 90^\circ \), S as \( 180^\circ \) and W as \( 270^\circ \). Ideally \( \alpha \) is equal to \( \beta \). However, a distinction between \( \alpha \) and \( \beta \) was made to validate the developed methodology.

For \( \alpha \), first the triangle S-P\(_C\)-C is considered:

\[
\cos \alpha = \frac{v_x \Delta t_S}{x} \tag{1}
\]

The second equation for \( \alpha \) is obtained from the triangle C-P\(_E\)-E:

\[
\cos(90^\circ - \alpha) = \frac{v_x \Delta t_E}{x} = \sin \alpha \tag{2}
\]

Dividing Equation (2) by Equation (1) leads to

\[
\frac{\sin \alpha}{\cos \alpha} = \frac{\Delta t_E}{\Delta t_S} = \tan \alpha \quad \text{and} \quad \alpha = \arctan \left( \frac{\Delta t_E}{\Delta t_S} \right) \tag{3}
\]

Now that \( \alpha \) is known, the propagation speed \( v_x \) (in m s\(^{-1}\)) of the inclining air pressure wave can be calculated:

\[
v_x = \frac{x}{\Delta t_S} \cos \alpha \tag{4}
\]

Using triangles C-P\(_W\)-W and N-P\(_C\)-C, \( \beta \) and the propagation speed \( v_y \) (in m s\(^{-1}\)) of the emerging air pressure wave can be determined:

\[
\cos \beta = \frac{v_y \Delta t_N}{x} \tag{5}
\]

\[
\sin \beta = \frac{v_y \Delta t_W}{x} \tag{6}
\]

\[
\beta = \frac{\Delta t_N}{\Delta t_W} \tag{7}
\]

\[
v_y = \frac{x}{\Delta t_N} \cos \beta \tag{8}
\]

From \( \alpha \) and \( \beta \), and \( v_x \) and \( v_y \), a mean direction of propagation \( \bar{\theta} \) (in \(^\circ\)) and a mean propagation speed \( \bar{v} \) (in m s\(^{-1}\)) was calculated (Berens, 2009).

These calculations were also done for the other possible propagation directions, leading to similar equations.

All 30 min intervals with a difference between \( \alpha \) and \( \beta \) larger than \( 10^\circ \) were excluded from further analysis (<10% of all 30 min intervals). This was necessary to assure a consistent calculation of \( \bar{\theta} \), since large changes in propagation direction over a few metres were assumed to be implausible.

In addition, PPC which describes the strength of pressure pumping, was calculated (Mohr et al., 2016):

\[
PPC = F_s \frac{1}{N} \sum_{n=1}^{N} |\Delta p| \tag{9}
\]

with the sampling frequency \( F_s \) (in Hz), the number of pressure measurements \( N \) in a 30 min interval and the air pressure difference between two subsequent measurements \( \Delta p \) (in Pa).

2.4.2. Airflow data. Wind vector data were despiked (Mohr and Schindler, 2016) and the mean wind speed \( \bar{U} \) (in m s\(^{-1}\)), mean horizontal wind speed \( \bar{U}_{\text{hor}} \) (in m s\(^{-1}\)) and the mean wind direction \( \bar{\Theta} \) (in \(^\circ\)) were calculated for all measurement heights (Berens, 2009).

3. Results and discussion

3.1. Direction of propagation of air pressure fluctuations

Figure 2 shows \( \bar{\theta} \) versus the mean above-canopy (\( \bar{\Theta}_a \)) and below-canopy wind direction (\( \bar{\Theta}_b \)).

It is obvious that during the measurement period airflow from the south dominates. Only during a few intervals, northeastern and northwestern wind directions occur. It can be seen that \( \bar{\theta} \) strongly (coefficient of determination \( R^2 = 0.98 \)) correlates to \( \bar{\Theta}_a \) (Fig. 2a). Similar correlations can also be found for \( \bar{\Theta}_b \) and \( \bar{\Theta}_c \). In contrast, the air pressure fluctuations do not seem to be connected to below-canopy airflow (Fig. 2b).

These results are in accordance with a previous study. Sigmon et al. (1983) who deduced the direction of propagation of air pressure fluctuations in a deciduous forest also reported that the
fluctuations propagate in the same direction as the mean above-canopy wind direction.

### 3.2. Propagation speed of air pressure fluctuations

Figure 3 shows an increase of \( \bar{v} \) with increasing \( U_{\text{hor},3} \) and \( U_{\text{hor},5} \). Values of \( \bar{v} \) are in the order of \( U_{\text{hor},5} \) (up to 6.5 m s\(^{-1}\)). The strong correlation between \( \bar{v} \) and \( U_{\text{hor},5} \) (\( R^2 = 0.83 \)) indicates that there is a connection between the observed air pressure fluctuations at the forest floor and the above-canopy airflow. The connection between \( U_{\text{hor},1} \) and \( \bar{v} \) is much less pronounced.

### 3.3. Spatial variability of the air pressure fluctuations

Figure 4 shows \( xcf_{\text{max}} \) between the air pressure signals from two pressure sensors as a function of \( d \).

It is clear that \( xcf_{\text{max}} \) strongly decreases with increasing \( d \). Only for \( d < 15 \) m, \( xcf_{\text{max}} > 0.90 \), corresponding to \( R^2 = 0.81 \). This demonstrates that the same air pressure fluctuations were measured within a distance of 15 m. At \( d > 15 \) m, the differences between the air pressure fluctuations increased significantly. This increase is attributed to amplitude changes and frequency shifts between the two air pressure signals.

### 3.4. Spatial variability of PPC

Although the differences between air pressure fluctuations strongly increase when \( d > 15 \) m, their envelopes stay similar. Thus, it was investigated if the dependence of PPC on \( \bar{U}_3 \) varies when \( d \) is changed. In Fig. 5 the dependence of PPC on \( \bar{U}_3 \) is shown for \( d = 0, 35 \) and 90 m.

Following Mohr et al. (2016), quadratic fits were calculated for the description of the dependences of PPC on \( \bar{U}_3 \) for the different distances:

\[
y_{\text{fit}, 0 \ m} = 0.03814 \bar{U}_3^2 - 0.03306 \bar{U}_3 + 0.01218 \tag{10}
\]

\[
y_{\text{fit}, 35 \ m} = 0.03892 \bar{U}_3^2 - 0.03586 \bar{U}_3 + 0.01333 \tag{11}
\]

\[
y_{\text{fit}, 90 \ m} = 0.03946 \bar{U}_3^2 - 0.03395 \bar{U}_3 + 0.01233 \tag{12}
\]
4. Conclusions

For the first time, the direction and the speed of propagation of air pressure fluctuations responsible for pressure pumping above a forest floor were identified. The air pressure fluctuations propagate in the same direction as the above-canopy airflow and not in the direction of below-canopy airflow. Moreover, the mean propagation speed of the air pressure fluctuations is in the same order as the mean above-canopy wind speed (up to 6.5 m s\(^{-1}\)) and increases with increasing mean above-canopy wind speed. These findings indicate that above-canopy airflow is linked to below-canopy air pressure fluctuations that influence soil gas transport through pressure-pumping.

Within a radius of 15 m the same strong peaks of the air pressure fluctuations were observed, but with time lags up to several seconds. The dependence of the pressure pumping coefficient on the mean above-canopy wind speed stays constant within a distance of 90 m.

This result specifies the range of influence of the air pressure fluctuations and helps to assess the number of air pressure measurements needed for the investigation of the influence of pressure pumping on soil gas transport at the measurement site.
