Abstract. Overhead irrigation is widely used to water lettuce during commercial production in China but exerts potential water wastage and pollution. Subirrigation is thought as a water-saving, high-efficiency fertigation strategy. However, few studies have compared the nutritional value and nitrate content of lettuce grown using subirrigation with plants cultivated with overhead irrigation. Therefore, this study explored the ability of ebb-and-flow subirrigation strategies to produce high yields of a leafy lettuce (cultivar Biscia Rossa) with high nutritional value and low nitrate content. Lettuce plants were cultivated in an ebb-and-flow subirrigation system with different irrigation frequencies (every 2 or 3 days) and immersion times (5, 10 or 15 minutes); overhead irrigation was used as control. Ebb-and-flow subirrigation significantly enhanced several lettuce growth parameters, significantly increased the level of vitamin C, and significantly decreased the nitrate content of lettuce leaves compared with overhead irrigation. The optimal subirrigation strategy for lettuce production was irrigation every 3 days with 15 minutes immersion; this ebb-and-flow subirrigation protocol could potentially be used to save water and resources, improve yield and nutrient contents and reduce nitrate content in commercial greenhouse lettuce production.

In horticultural practice, numerous factors—such as environmental conditions, agricultural management, harvest time, and irrigation and fertilization strategies—affect the production and chemical composition of vegetable crops (Tavarini and Angelini, 2013). Water management is a key determinant of both the biomass and nutritional composition of vegetables cultivated in greenhouses.

China is a major producer of the salad vegetable lettuce (Lactuca sativa L.); China is responsible for 56% of worldwide lettuce (and chicory) production (United Nation Food and Agriculture Organization, 2016). Overhead irrigation is widely used to water lettuce during commercial production as it has a low equipment cost and is thought to beneficially decrease accumulation of fertilizer salinity (Argo and Biernbaum, 1995). However, overhead irrigation also has negative effects, e.g., water wastage and potential pollution of the soil surface and groundwater with pesticides and fertilizers (Ferrarezi et al., 2015a). Therefore, the challenge remains to develop environmentally friendly irrigation management techniques that enable optimal crop production.

Subirrigation is a water-saving, high-efficiency fertigation strategy in which intelligent control enables sustainable use of both water and fertilizers; however, the initial cost of automated subirrigation systems is high (Ferrarezi et al., 2015a; Thomas, 1993). Ebb-and-flow subirrigation is relatively cheap and easy-to-use compared with other subirrigation systems and is recognized as a high water productivity strategy. Ebb-and-flow system can adjust the water and fertilizer depending on the requirement of crop and reduce the overall water and nutrient use (Ferrarezi et al., 2015b). For instance, Holcomb et al. (1992) reported that ebb-and-flow systems reduce the use of water and fertilizer by 40% in the production of Hedera helix. In addition, ebb-and-flow systems have been associated with lower occurrence of foliar and soil-borne diseases and groundwater contamination (Thomas, 1993). Moreover, automatic control of fertigation reduces labor costs and provides a potential economic benefit (Ferrarezi et al., 2015a).

Lettuce is a significant source of many nutrients and has been reported to exert antioxidant (Yang et al., 2017), anthepatis B virus (Cui et al., 2017), anti-inflammatory (Pepe et al., 2015), and anti-diabetic (Cheng et al., 2014) effects. However, leafy vegetables, such as spinach and lettuce, represent significant sources of nitrate in the human diet, providing ≈40% to 92% of the average daily intake of nitrate and its metabolite nitrite (14% to 43% of daily dietary intake) (Liu et al., 2014; Qadir et al., 2017). Therefore, high levels of nitrate in lettuce crops may be harmful to human health because of the toxicity of its downstream metabolites nitrite, nitrosamines, and nitrosamides (Santamaria, 2006).

Numerous studies have investigated the nutrient requirements, water use, and growth of lettuce cultivated in ebb-and-flow systems. Soundy et al. (2001a, 2001b) suggested appropriate concentrations of phosphorus and potassium after lettuce transplantation using an ebb-and-flow system. Ahmed et al. (2000) reported ebb-and-flow subirrigation led to significantly taller lettuce plants and saved ≈86% of the water used by overhead irrigation. However, little research has compared the nutritional value and nitrate content of lettuce grown using an ebb-and-flow system with plants cultivated with overhead irrigation.

In this study, we aimed to develop an ebb-and-flow subirrigation strategy for commercial greenhouse lettuce production that results in high yields of healthy plants with high contents of potentially health-promoting compounds—such as vitamin C, chlorophyll, sugar, and proteins—and a safe nitrate content.

Materials and Methods

Subirrigation System. The ebb-and-flow subirrigation system used in this study consisted of three layers of waterproof benches,
an electric timer, a fertilizer solution reservoir, an artificial lighting system, and a pump. The length, width, and height of the system were 6.5 m, 0.6 m, and 1.8 m, respectively. The three cultivation benches in each layer were periodically flooded with water (or water-soluble fertilizer solution) using the pump. Each bench was 2 m long, 0.6 m wide and 0.06 m deep. The slice gap of each layer is 0.8 m.

Plant materials. Seeds of the widely cultivated, relatively high economic value, purple leaf lettuce cultivar Biscia Rossa were purchased from Franchi Sementi Ltd. Co., Milan, Italy. Seeds were sown in 200-hole trays (one seed per hole) in seedling substrate (NPK ≥2%, organic matter ≥40%; Zhongnuo Agriculture R&D Company, Huai’an, China) in the ebb-and-flow system in a greenhouse at the Shanghai Jiao Tong University, China (lat. 31°12’N, long. 121°38’E). Fourteen-day-old seedlings with the third true leaves were transplanted into trapezoidal plastic containers (sides: 20 × 20 cm; base: 20 × 12 cm; height, 12 cm) containing 15% organic fertilizer (NPK ≥6%, organic matter ≥45%; Zhongnuo) and 85% seeding substrate.

Various ebb-and-flow system subirrigation strategies lasting 30 d with different irrigation frequencies and immersion times were programmed: irrigation every 2 d with 5 min immersion; 2d/10 = every 2 d with 10 min immersion; 2d/15 = every 2 d with 15 min immersion; 3d/5 = every 3 d with 5 min immersion; 3d/10 = every 3 d with 10 min immersion; 3d/15 = every 3 d with 15 min immersion. Control plants were subjected to overhead irrigation. Values are mean ± SD of five replications. Different letters represent significant differences at P < 0.05 (least significant difference). 2d/5 = every 2 d with 5 min immersion; 2d/10 = every 2 d with 10 min immersion; 2d/15 = every 2 d with 15 min immersion; 3d/5 = every 3 d with 5 min immersion; 3d/10 = every 3 d with 10 min immersion; 3d/15 = every 3 d with 15 min immersion.

Table 1. Plant growth characteristics of lettuce subjected to different ebb-and-flow subirrigation strategies.

| Treatment | Fresh wt (g/plant) | Dry wt (g/plant) | Plant ht (cm) | Leaf length (cm) | Leaf width (cm) | Water content (%) |

Control plants were subjected to overhead irrigation. Values are mean ± SD of five replications. Different letters represent significant differences at P < 0.05 (least significant difference). 2d/5 = every 2 d with 5 min immersion; 2d/10 = every 2 d with 10 min immersion; 2d/15 = every 2 d with 15 min immersion; 3d/5 = every 3 d with 5 min immersion; 3d/10 = every 3 d with 10 min immersion; 3d/15 = every 3 d with 15 min immersion.

Fig. 1. Effect of different ebb-and-flow subirrigation strategies on the (A) total chlorophyll content and (B) anthocyanin content of lettuce leaves. Control plants were subjected to overhead irrigation. Values are mean ± SD of three replications (n = 3 each). Different letters represent significant differences at P < 0.05 (least significant difference analysis).

Protein content was determined by Coomassie Brilliant Blue G-250 staining (Wang and Xing, 2009). Leaf samples (0.5 g) were homogenized in 5 mL of distilled water, centrifuged at 4000 rpm for 10 min, and 10 μL supernatant was added to 5 mL Coomassie Brilliant Blue G-250 solution (100 mg dissolved in 50 mL ethanol, 100 mL 85% phosphoric acid was added, then diluted to 1 L with water). Absorption was assessed at 595 nm using an ultraviolet–vis spectrophotometer and protein content was determined using a standard curve created using bovine serum albumin.

Determination of vitamin C content and nitrate concentration. Vitamin C content was determined as previously described (Francisco et al., 2010). Briefly, leaf tissues (0.1 g) were placed in a 15-mL tube containing 5 mL of 80% acetone and 5 mL of 100% ethanol and incubated in the dark at room temperature until the tissues became white. Absorbance was measured at 663, 646, and 470 nm. A solution of 80% acetone and 100% ethanol (1/1, v/v) was used as the blank control.

Anthocyanin content was determined using the pH differential method (Yang, 2007). Briefly, 1.0 mL of 1.0% HCl/methanol was added to 300 mg of freshly ground leaf material, incubated at room temperature for 18 h with gentle agitation, centrifuged at 14,000 rpm for 1 min, and 400 mL of cleared supernatant was mixed with 600 mL of acidified methanol. Two dilution tubes of 5 mL of each sample were prepared. One was added to 4 mL of KCl solution (pH 1) and the other was added to 4 mL of CH3COONa (pH 4.5). The absorption values of each sample were determined at the λmax (530 nm in this study) and 700 nm using a double beam ultraviolet–vis spectrophotometer. The anthocyanin content was expressed as the equivalent of cyanidin-3-glucoside in mg per g FW.

Determination of soluble sugar and soluble protein content. To analyze soluble sugars, 1 g of leaf tissue was extracted in 4 mL of 80% ethanol, heated in a boiling water bath for 30 min, cooled, centrifuged at 3000 rpm for 10 min, and the absorbance value of the supernatant was determined at 620 nm (Lin, 1989). The concentration of soluble sugars was calculated by reference to a standard curve created using glucose.

The nitrate contents of dried samples were analyzed following the method described by Powell et al. (2000). Briefly, 0.5 g root tips, 5.0 mL of 2,3,5-triphenyltetrazolium chloride solution (0.4%), and 5.0 mL of phosphate buffer were incubated at 37 °C for 3 h, then 2.0 mL of H2SO4 (1.0 M) was added to end the reaction and absorbance was assessed at 485 nm.

Statistical analysis. Data were analyzed using SPSS 14.0 software (IBM, Armonk,
Differences among means were compared by the least significant difference test; \( P < 0.05 \) was considered significant. The correlation was assessed using two-tailed Pearson correlation tests; \( P < 0.01 \) and \( 0.05 \) were considered significant. Figures were created using OriginPro 2016 software (OriginLab, Northampton, MA).

**Results**

Effects of ebb-and-flow subirrigation strategies on the morphological characteristics, fresh and dry weights and water content of lettuce. The plant growth characteristics of lettuce subjected to different irrigation strategies are shown in Table 1. Compared with control lettuce cultivated with overhead irrigation, all ebb-and-flow treatments significantly (\( P < 0.05 \)) increased FW. At the same irrigation frequency, longer immersion times led to significantly higher FWs. In addition, plants irrigated every 3 d had significantly higher FWs than plants irrigated every 2 d. Lettuce in the 2d/5, 3d/10, and 3d/15 treatments had significantly higher DWs than control plants. The highest FW was observed for the 3d/15 treatment, which was 2.3-fold higher than control; the highest DW in 3d/10 treatment was 1.8-fold higher than control lettuce. Water content was significantly higher for the 2d/10, 2d/15, and 3d/15 treatments than control. Moreover, water content was significantly higher for plants irrigated every 2 d than plants irrigated every 3 d except for treatments with immersion for 5 min.

The various ebb-and-flow subirrigation strategies had a significantly increased effect on the plant height and leaf length and width compared with control plants (Table 1). The 3d/15 ebb-and-flow subirrigation treatment led to the largest plant height, leaf length, and leaf width values (17.93 cm, 17.13 cm, and 7.23 cm); these values were 1.2-, 1.4- and 1.3-fold higher than control plants.

Effects of ebb-and-flow subirrigation strategies on the pigment contents of lettuce. Compared with control lettuce, the 2d/5 ebb-and-flow treatment led to a significantly lower total chlorophyll content, the 3d/15 treatment led to the highest total chlorophyll content, and the other ebb-and-flow treatments did not significantly affect total chlorophyll content (Fig. 1A).

All ebb-and-flow subirrigation treatments led to significantly lower anthocyanin contents compared with control lettuce; the 3d/15 treatment led to the highest anthocyanin content among ebb-and-flow irrigated lettuce (0.21 mg/g FW; Fig. 1B).

Effects of ebb-and-flow subirrigation strategies on the nutrient contents of lettuce. Ebb-and-flow irrigation treatments led to higher ascorbic acid contents than control lettuce, although the difference between the 3d/15 treatment and control plants was not significantly different (Fig. 2A).

Lettuce in the 3d/5 and 3d/10 treatments had significantly higher protein contents than control plants, corresponding to 1.2- and 1.1-fold increases, respectively (Fig. 2B). No significant difference in soluble sugar content was observed between control plants and most ebb-and-flow subirrigation treatments, although the 2d/15 treatment led a significantly lower soluble sugar content (Fig. 2C).

![Fig. 2. Effect of different subirrigation strategies on (A) vitamin C content, (B) protein content, and (C) soluble sugar content of lettuce leaves. Control plants were subjected to overhead irrigation. Values are mean ± so of three replications (n = 3 each). Different letters represent significant differences at \( P < 0.05 \) (least significant difference analysis).](image-url)
Effects of ebb-and-flow subirrigation strategies on the nitrate concentration of lettuce. As shown in Fig. 3, all ebb-and-flow subirrigation strategies led to significantly lower nitrate concentrations compared with control lettuce plants which were irrigated overhead. The lowest nitrate concentration was observed in the 2d/10 treatment (44.60% lower than control).

**Discussion**

Sustainable water use mainly depends on agriculture water use. Therefore, developing a proper agricultural water management system is necessary (Shalrokhnia and Sepas-khah, 2016). Subirrigation systems have been developed to enable the more economic use of water and fertilizer, enhance crop production efficiency, and maintain crop yield. The water is directly transferred into the plant growth substrate in ebb-and-flow systems, and this technique has been proven to reduce water input in comparison with overhead irrigation (Davis et al., 2011). In this study, the ebb-and-flow subirrigation method decreased water consumption by 33% and improved water use efficiency by 20% compared with conventional overhead irrigation. Reduced water use in vegetable production is beneficial, as water costs are a major expense in greenhouse crop production.

We found the ebb-and-flow subirrigation strategies significantly increased lettuce plant growth and biomass compared with control overhead irrigation. Moreover, Pearson correlation analysis suggested the ebb-and-flow subirrigation treatments correlated positively with the FW ($r = 0.86, P < 0.01$) and leaf length ($r = 0.67, P < 0.01$) of the lettuce. These results are in accordance with studies of other plant species, including tomato seedlings, cotoneaster, and forsythia, which suggested subirrigation led to higher biomass than overhead irrigation (Ahmed et al., 2000; Hicklenton and Cairns, 1996). One explanation may be the reduced water stress and greater nutrient retention in plants exposed to subirrigation (Ahmed et al., 2000; Hicklenton and Cairns, 1996). At the same immersion times, 3 d-irrigation led to higher lettuce FW and DW than irrigation every 2 d. The 3d/15 treatment (irrigated every 3 d with 15 min immersion) led to optimal lettuce growth, with the highest FW, plant height, leaf length, and leaf width. The increased immersion time may lead to a higher water content in the substrate, which may improve water absorption and usage by plants (Li et al., 2014). Similarly, a previous study in maize reported that a low frequency of irrigation resulted in higher yields than a higher frequency of irrigation and also reduced costs and enhanced water use efficacy (Wang et al., 2008). Pearson correlation analysis suggested lettuce FW correlated positively ($r > 0.75$) with plant growth parameters, including plant height ($r = 0.80, P < 0.01$), leaf length ($r = 0.90, P < 0.01$), and leaf width ($r = 0.82, P < 0.01$), although lettuce FW correlated weakly with water content ($r = 0.54, P < 0.05$) and other nutrient contents ($r < 0.50$).

Anthocyanidins help to protect photosynthetic organs from damage by ultraviolet radiation and the anthocyanidin content is positively related to plant stress resistance capability (Chalker-Scott, 1999). In this study, ebb-and-flow subirrigation led to significantly lower anthocyanidin contents than lettuce subjected to overhead irrigation. These findings are in line with the growth-differentiation balance hypothesis (Glynn et al., 2007), which states plants tend to favor vegetative growth under conditions of sufficient water and fertilization (e.g., the subirrigation treatments in this study) over synthesis of stress resistance compounds (e.g., anthocyanidins and flavonoids). The vital photosynthetic pigment chlorophyll is positively correlated with assimilation productivity (Cendero-Mateo et al., 2015). In this study, the total chlorophyll contents of lettuce were slightly (but not significantly) higher in the 2d/10, 2d/15, 3d/5, and 3d/10 treatments, and the 3d/15 treatment led to significantly higher chlorophyll accumulation. Therefore, the higher total chlorophyll contents and lower total anthocyanidin contents suggest subirrigation leads to better vegetative growth in lettuce than overhead irrigation, which partially explains the significantly higher FW of the subirrigated lettuce.

The soluble protein content was significantly higher in the 3d/5 and 3d/10 treatments than the other subirrigation treatments and control lettuce, indicating some soluble proteins may be induced as a protective mechanism in plants suffering water insufficiency (Bray, 1997). The subirrigation treatments significantly increased the ascorbic acid content compared with control lettuce (except in the 3d/15 treatment), whereas the soluble sugar content was not significantly different between most subirrigation treatments and control lettuce. Moreover, irrigation every 3 d led to higher soluble sugar and protein contents than irrigation every 2 d; and as immersion time increased, the soluble sugar, vitamin C, and protein contents decreased. These results are in accordance with previous studies (Liu et al., 2001, 2006; Zushi and Matuszoc, 1998) that suggested lower irrigation frequencies and volumes, which reduce soil or substrate water contents, increase nutrient levels (e.g., vitamin C and soluble sugar) in fruit.

Nitrate reductase reduces nitrate to nitrite; this reaction is thought to be the rate-limiting step of plant nitrogen assimilation. However, a relatively low water content in plants decreases nitrate reductase activity and may result in increased accumulation of nitrate (Foyer et al., 1998). In this study, ebb-and-flow subirrigation led to significantly lower nitrate concentrations compared overhead irrigation; the lower water content of control plants may decrease nitrate reductase activity and lead to increased accumulation of nitrate (Foyer et al., 1998). In addition, the roots are the major site of plant nitrate assimilation. Compared with overhead irrigation, ebb-and-flow subirrigation strategies led to higher numbers of roots and lower root nitrate concentrations than Pelargonium hortorum grown with overhead irrigation, suggesting plants subjected to subirrigation may have a higher capability to assimilate nitrate (Morvant et al., 1997).
Lettuce can absorb and accumulate large quantities of nitrate that could potentially be harmful to human health (Santamaria, 2006). The products of nitrate reduction (nitrite and conversion (nitrosamines and nitrosamides) are toxic (Umar and Iqbal, 2007). Some pediatric diseases, such as acute respiratory tract infections (Gupta et al., 2000), recurrent diarrhea (Gupta et al., 2001), and recurrent stomatitis (Gupta et al., 1999), have been associated with high nitrate consumption. Moreover, consumption of high levels of nitrate has negative effects on cardiac muscles, adrenal glands, lung alveoli, and the immune system in humans (Gupta et al., 2006; Ustyugova et al., 2002), and is associated with infant mortality, hypothyroidism, and diabetes (Gupta et al., 2006). Excitingly, we found the ebb-and-flow subirrigation treatments significantly decreased the total nitrate concentration in lettuce compared with overhead irrigation. Thus, subirrigation strategies could potentially benefit human nutrition by enabling the production of lettuce with low nitrate levels.

Based on plant growth characteristics, FW and DW, nutritional value, and nitrate content, the 3d/15 treatment (irrigation every 3 d, 15 min immersion) was the optimal ebb-and-flow subirrigation strategy for lettuce cultivation. This irrigation strategy led to the highest FW, a high total chlorophyll content, high concentrations of nutrients (such as vitamin C, soluble proteins, and sugars), and moderate anthocyanidin and nitrate contents. Further investigation of this subirrigation strategy in leafy vegetable production is required before this system can be used operationally. For instance, strategies to avoid the potential spread of root-infecting pathogens during cultivation and the optimal conditions (including lighting, fertigation, plant growth regulators and pesticides) for lettuce production need to be determined.

Conclusion

Ebb-and-flow subirrigation significantly increased plant growth and vitamin C contents and significantly decreased the nitrate content of lettuce. We found that a 15-min immersion every 3 d was the optimal ebb-and-flow subirrigation treatment; this strategy could potentially be used in commercial lettuce production.
