Things that can be made into themselves

Abstract

One says that a property $P$ of sets of natural numbers can be made into itself iff there is a numbering $\alpha_0, \alpha_1, \ldots$ of all left-r.e. sets such that the index set $\{ e : \alpha_e \text{ satisfies } P \}$ has the property $P$ as well. For example, the property of being Martin-Löf random can be made into itself. Herein we characterize those singleton properties which can be made into themselves. A second direction of the present work is the investigation of the structure of left-r.e. sets under inclusion modulo a finite set. In contrast to the corresponding structure for r.e. sets, which has only maximal but no minimal members, both minimal and maximal left-r.e. sets exist. Moreover, our construction of minimal and maximal left-r.e. sets greatly differs from Friedberg’s classical construction of maximal r.e. sets. Finally, we investigate whether the properties of minimal and maximal left-r.e. sets can be made into themselves.

Keywords: numberings, self-reference, minimal left-r.e. sets, maximal left-r.e. sets, Martin-Löf random sets.

1. Introduction

The roots of recursion theory entwine self-reference. Even before Turing \cite{43} formalised the notion of computation using machines with infinite tapes and finite control structures, mathematicians conceived of primitive recursive and recursive functions \cite{1, 20}. In particular, Kurt Gödel captured many aspects of computation in his formal system of arithmetic and exploited its self-referential properties in the proof of his famous incompleteness theorem.

In order to show that the theory of natural numbers does not have a consistent and complete r.e. axiomatization, Gödel created a first-order formula which informally states, with respect to an underlying primitive-recursive set of axioms,

“This statement is unprovable.”

so that neither the statement nor its negation has a mathematical proof with respect to the given set of axioms. Gödel’s ground-breaking construction contained various important concepts including coding, or numbering, techniques. For this reason the acceptable numberings are also called, after him, *Gödel numberings*. The expressive strength of a general-purpose computer language is precisely what makes Gödel’s self-referential statement possible. Self-reference has manifested itself in computer science and mathematics in the form of fixed point theorems, in particular Kleene’s Recursion Theorem [24], Roger’s Fixed-Point Theorem [38, Theorem 11-I], the Arslanov Fixed Point Theorem [3] and its generalizations [3, 4, 22], as well as other diagonalization methods [33, 40]. Today research continues in the area of machine self-reference and self-knowledge [10].

In recursion theory one often studies effective listings of r.e. sets and partial-recursive functions. On one hand there are the acceptable numberings introduced by Gödel [20]; on the other hand Friedberg [18] showed that there are also one-one numberings of the above named objects where each item occurs exactly once. In this paper, we look at self-reference in terms of numberings of left-r.e. sets. Here a set $A$ is left-r.e. iff it can be approximated by a uniformly recursive sequence of sets such that $A$ is the lexicographic supremum of all these sets. Furthermore, a left-r.e. numbering $A_0, A_1, \ldots$ is an effective sequence of left-r.e. sets as defined more precisely below (Definition 1.2). Numberings for left-r.e. sets were first studied by Brodhead and Kjos-Hanssen [7, 23] and provide more expressive possibilities than the traditional numberings for r.e. sets.

In this paper, we are especially interested in classes $\mathcal{C}$ of sets such that there is a numbering of all left-r.e. sets in which the index set of the left-r.e. members of $\mathcal{C}$ is itself a member of the class $\mathcal{C}$. For some reason such things exist, and we call this phenomenon “things that can be made into themselves.” Here the phrase “can be made into themselves” implicitly refers to the fact that we permit ourselves the flexibility to choose the underlying numbering of all left-r.e. sets for a desired purpose. If we would follow the usual default and use only acceptable left-r.e. numberings, this would prohibit
many things from being made into themselves. Indeed Rice’s Theorem \[36\] holds for acceptable left-r.e. numberings and therefore any non-trivial index set is many-one hard either for the halting problem or its complement.

In 1958, Friedberg \[18\] constructed a maximal r.e. set, that is, an r.e. set maximal under inclusion up to finite differences, thereby bringing Post’s program \[33, 35, 40\] to an abrupt halt. Post \[35\] had wished to prove the existence of Turing incomplete r.e. sets by building sets with sparse complements. Maximal sets can be Turing complete and have the thinnest possible complements for r.e. sets, so Friedberg’s result shows that “thinness” alone cannot achieve Turing incompleteness. As independently discovered by Friedberg \[19\] and Muchnik \[40\], Turing incomplete r.e. sets do exist by alternate methods. In Section 6 we introduce the concept of maximal and minimal left-r.e. sets. Unlike the class of r.e. sets, which has only maximal sets, both minimal and maximal left-r.e. sets exist (Theorem 6.2). Maximal r.e. sets cannot be maximal left-r.e (Theorem 6.3), and among the minimal and maximal left-r.e. sets only singleton maximal left-r.e. sets can be made into themselves (Theorem 6.5).

We shall show that the Martin-Löf random sets and 1-generic sets can be made into themselves (Corollary 2.5 and Corollary 2.7), though not at the same time (Proposition 5.2), whereas the r.e., co-r.e. and recursive sets each cannot be (Corollary 3.2). We characterise the left-r.e. sets whose index sets can be made equal to the set itself (Theorem 4.1) and discuss the complexity of the inclusion problem for left-r.e. numberings (Theorem 7.1).

**Notation 1.1.** A numbering $\varphi$ of partial-recursive functions is a mapping $e \mapsto \varphi_e$ such that the induced mapping $(e, x) \mapsto \varphi_e(x)$ is partial-recursive. $W_e^\varphi$ denotes the domain of $\varphi_e$ and we may omit the superscript when it is clear from context. We identify numbers in a one-one way with binary strings so that the ordering of the numbers is translated into the length-lexicographic ordering of the strings. We use $|e|$ to denote the length of the string $e$, and we shall appeal to the fact that $|e| \leq 1 + \log e$ for all $e > 0$.

Let a machine $\psi$ be a partial-recursive mapping from strings to strings. The complexity of $x$ with respect to $\psi$, called $C_\psi(x)$ is the length of the shortest input $y$ with $\psi(y) = x$. $\psi$ is called universal iff its range contains all strings and for every further machine $\varphi$ there is a constant $c$ such that for all $y$ in the domain of $\varphi$, $C_\psi(\varphi(y)) \leq |y| + c$. It the field of Kolmogorov complexity, one fixes some plain universal machine and denotes with $C(x)$ the plain Kolmogorov complexity of $x$ with respect to this machine. Similarly,
one can consider prefix-free machines where a machine $\psi$ is prefix-free iff any two strings in its domain, neither of the two is a proper prefix of the other one. One can then define the prefix-free Kolmogorov complexity $H$ as above with respect to a fixed machine which is universal among all prefix-free machines. Calude \cite{8} and Li and Vitányi \cite{27} provide further background on Kolmogrov complexity.

Let $A \triangle B$ denote the symmetric difference of $A$ and $B$, that is, $A \cup B - A \cap B$. Furthermore, $\overline{A} = \mathbb{N} - A$ is the complement of the set $A$. Furthermore, $A \subseteq^* B$ means that almost all elements of $A$ are also in $B$ and $A \subset^* B$ means that in addition to the previous, there are infinitely many elements in $B - A$. For finite strings $\sigma$ and $\tau$, $\sigma \cdot \tau$ denotes concatenation of $\sigma$ and $\tau$, $\sigma \supseteq \tau$ means $\sigma$ extends $\tau$ and $\sigma \subseteq \tau$ means $\sigma$ is a prefix of $\tau$. Similarly for sets, $\sigma \supseteq A$ means that $\sigma$ is a prefix of $A$ (where, as usual, the set $A$ is identified with the infinite sequence $A(0)A(1)\ldots$ given by its characteristic function). A set is recursively enumerable (or just r.e.) iff it is either empty or the range of a recursive function. A set is co-r.e. if it is the complement of an r.e. set, $'$ is the jump operator and $\equiv_T$ is Turing equivalence. We say $A$ is $B$-recursive if $A \leq_T B$. $A \leq_{\text{bit}} B$ if membership in $A$ can be decided by uniformly constructing a Boolean formula over finitely many variables and evaluating it using membership values from $B$. For a set $A$, we use $A \upharpoonright n$ to denote the prefix of $A$'s characteristic sequence $A(0)A(1)\ldots A(n)$. A subset of natural numbers is $\Pi^0_n$ if it can be described by a formula consisting of $n$ alternating quantifiers, starting with a universal quantifier, and ending with a recursive predicate. Furthermore, a set is $\Sigma^0_n$ iff its complement is $\Pi^0_n$.

A set $A$ is called autoreducible \cite{42} if for all $x$, whether $x$ is a member of $A$ can be effectively determined by querying $A$ at positions other than $x$; a set $A$ is called strongly infinitely-often autoreducible \cite{2} if there is a partial-recursive function $\psi$ such that for all inputs of the form $x = A(0)\ldots A(n-1)$, either $\psi(x)$ outputs ? or $\psi(x)$ outputs $A(n)$ and the latter happens infinitely often; note that there are strongly infinitely often autoreducible sets which are not autoreducible. For any numbering $\alpha$, the $\alpha$-index set of a class $C$ is the set $\{e : \alpha_e \in C\}$. For sets of nonnegative integers $A$ and $B$, $A \leq_{\text{lex}} B$ means that either $A = B$ or the least element $x$ of the symmetric difference satisfies $x \in B$. A set $A$ is left-r.e. iff there is a uniformly recursive approximation $A_0, A_1, \ldots$ of $A$ such that $A_s \leq_{\text{lex}} A_{s+1}$ for all $s$. The symbol $\oplus$ denotes join. For further background on recursion theory and left-r.e. sets, see the textbooks of Calude \cite{8}, Downey and Hirschfeldt \cite{15}, Li and Vitányi \cite{27}, Nies \cite{32}, Odifreddi \cite{33, 34}, Rogers \cite{38} and Soare \cite{40}. 4
The reader may already be familiar with left-r.e. reals, which admit an increasing, recursive sequence of rationals from below, however in the context of effective enumerations it makes more sense to consider left-r.e. sets, see Section 2. For example, the infinite left-r.e. sets have an left-r.e. numberings while the coinfinite left-r.e. sets do not have one; if one would only consider left-r.e. reals, the distinction between coinfinite and infinite sets would disappear and so, for example, the coinfinite reals would have a left-r.e. numbering. So the results depend a bit on the setting (sets versus reals) and we decided to follow the more natural setting of sets (as most of recursion theory does).

**Definition 1.2.** A left-r.e. numbering $\alpha$ is a mapping from natural numbers to left-r.e. sets given as the limits of a uniformly recursive sequences in the sense

$$e \mapsto \lim_{s \to \infty} \alpha_{e,s} = \alpha_e$$

where the following two conditions hold:

1. the mapping $e, s, n \mapsto \alpha_{e,s}(n)$ is recursive and $\{0, 1\}$-valued;
2. $\alpha_{e,s} \leq_{\text{lex}} \alpha_{e,s+1}$ for all $s$.

A left-r.e. numbering is called universal if its range includes all left-r.e. sets, and a left-r.e. numbering $\alpha$ is called an $(K)$-acceptable left-r.e. numbering if for every left-r.e. numbering $\beta$ there exists a $(K)$-recursive function $f$ such that $\alpha_{f(e)} = \beta_e$ for all $e$. Here $K$ denotes the halting set.

Acceptable numberings permit an effective means for coding any algorithm, so an example of an acceptable numbering can be obtained by the functions defined in some general purpose programming language where some adjustments in definitions have to be made, for example, that variables take as values natural numbers and that there is exactly one input and one output and that there are no constraints on the size of the numbers stored in the variables; furthermore, the program texts have to be identified with natural numbers coding them and ill-formed programs just correspond to the everywhere undefined function.

**Definition 1.3.** We say that a class of sets $C$ can be made into itself if there exists a universal left-r.e. numbering $\beta$ such that

$$\{e : \beta_e \in C\} \in C.$$
Note that in this context there are classes $\mathcal{C}$ which can be made into themselves and which do not entirely consist of left-r.e. sets. This will be essential for various results; for example the Martin-Löf random sets can be made into themselves (Corollary 2.5) while the Martin-Löf random left-r.e. sets cannot be made into themselves (Proposition 3.3). Hence permitting $\mathcal{C}$ to have members which are not left-r.e. is often necessary and is also natural in the case for many classes.

Our primary tool for making things into themselves will be indifferent sets. An indifferent set is a list of indices where membership in a given set can change without affecting membership in some class.

**Definition 1.4** (Figueira, Miller and Nies [16]). An infinite set $I$ is called indifferent for a set $A$ with respect to $\mathcal{C}$ if for any set $X$,

$$X \Delta A \subseteq I \implies X \in \mathcal{C}.$$ 

When the class $\mathcal{C}$ is clear from context, we may omit it.

### 2. Classes that can be made into themselves

We show that any class of nonrecursive sets which either contains the Martin-Löf random sets or contains the weakly 1-generic sets can be made into itself. Our proof relies crucially on co-r.e. indifferent sets which are retraceable by recursive functions.

A set $A$ is called *Martin-Löf random* [28, 39] if there exists a constant $c$ such that for all $n$, $H(A \upharpoonright n) \geq n - c$. Intuitively, $A$ is random if every prefix of $A$ is incompressible and therefore lacks a simple pattern. Zvonkin and Levin [45] and later Chaitin [12] gave an example of a left-r.e. Martin-Löf random real called $\Omega$.

Figueira, Miller and Nies [16] constructed indifferent sets for the class of Martin-Löf random sets. One of their approaches is to build indifferent sets for non-autoreducible sets. While this works for Martin-Löf random sets, the technique does not generalise to weaker forms of randomness because recursively random sets may be autoreducible [29]. On the other hand, Franklin and Stephan [17] showed that every complement of a dense simple set is indifferent with respect to Schnorr randomness for all Schnorr random sets. The arguments in Lemma 2.2 and Theorem 2.4 are also essentially due to Figueira, Miller and Nies [16], however we find it useful to make explicit the property of retraceability.
Definition 2.1. A set \( A = \{a_0, a_1, a_2, \ldots\} \) is retraceable if there exists a partial-recursive function \( f \) satisfying \( f(a_{n+1}) = a_n \) for all \( n \) and \( f(x) < x \) whenever \( f(x) \) is defined. A set \( S \) is approximable if there exists an \( n \) and a recursive function \( f \) such that for any \( x_1, \ldots, x_n \) with \( x_1 < \ldots < x_n \), \( f(x_1, \ldots, x_n) \in \{0, 1\}^n \) and \( f(x_1, \ldots, x_n) \) agrees with the characteristic vector \( \langle S(x_1), \ldots, S(x_n) \rangle \) in at least one place. More generally, if agreement in not only one but \( m \) places is required, we say \( S \) is \((m, n)\)-recursive, where \( 1 \leq m \leq n \).

Lemma 2.2. For every \( K \)-recursive function \( f \), there exists a co-r.e. set \( I = \{i_0, i_1, i_2, \ldots\} \) which is retraceable by a recursive function and satisfies \( f(n) < i_n < i_{n+1} \) for all \( n \).

Proof. Let \( \{f_s\} \) be a recursive approximation to \( f \) satisfying \( \max f_s < s \). We construct \( I \) by a movable marker argument. The set 
\[
I_s = \{i_{0,s}, i_{1,s}, i_{2,s}, \ldots\}
\]
will be a recursive approximation to \( I \) at stage \( s \). Set \( I_0 = \omega \). At stage \( s + 1 \), choose the least \( n \) satisfying \( f_s(n) \neq f_{s+1}(n) \) and enumerate sufficiently many elements into \( T_{s+1} \) such that

- For all \( k \geq n \), \( i_{k,s+1} \geq s + 1 \), and
- For all \( k < n \), \( i_{k,s+1} = i_{k,s} \).

For each \( n \), \( \{f_t(n)\} \) settles in some stage \( s_n + 1 \) and so
\[
i_n = i_{n,s_n} \geq s_n + 1 > f(n).
\]
Furthermore, the recursive function
\[
g(x) = \begin{cases} 
i_0 & \text{if } x \leq i_1, \\
\max I_{x+1} \cap \{0, 1, 2, \ldots x - 1\} & \text{otherwise.}
\end{cases}
\]
witnesses that \( I \) is retraceable because if \( I \) differs from \( I_{x+1} \) at some index below \( x + 1 \), then by construction \( x \notin I \) \( \square \).

The set in Lemma 2.2 is retraced by a total recursive function. Hence there is a recursive function \( h \) which maps \( I \) surjectively to the set of natural
numbers. In the above case, one can also see directly that such a \( h \) exists, as one can choose \( h \) as
\[
h(x) = |I_{x+1} \cap \{0, 1, \ldots, x\}|
\]
and then \( h \) has the desired property \( h(i_n) = n \). A set which is retraceable by a recursive function is \((1, 2)\)-recursive \([41]\), and therefore the set \( I \) above is also approximable.

**Lemma 2.3.** Let \( \mathcal{C} \) be a class of nonrecursive sets containing:

(i) a \( K \)-recursive member \( A \) with a co-r.e. and retraceable set \( I \) which is indifferent for \( A \) with respect to \( \mathcal{C} \) and

(ii) a left-r.e. set \( X = \sup X_s \) such that all the recursive approximations \( X_s \) to \( X \) satisfy \( \sigma \cdot X_s \notin \mathcal{C} \) while \( \sigma \cdot X \in \mathcal{C} \) for all strings \( \sigma \).

Let \( \mathcal{D} \) be a superclass of \( \mathcal{C} \) not containing any recursive set. Then there exists a \( K \)-acceptable universal left-r.e. numbering which makes \( \mathcal{D} \) into itself.

**Proof.** Let \( i_0, i_1, i_2, \ldots \) be the elements of \( I \) in ascending order and let the numbering \( \alpha_0, \alpha_1, \alpha_2, \ldots \) be an acceptable universal left-r.e. numbering. Recall that there is a recursive function \( h \) with \( h(i_n) = n \) for all \( n \). Let \( A_s \) be an approximation of \( A \) in the limit. Now define
\[
\beta_e = \begin{cases} 
\alpha_{h(e)} & \text{if } e \in I, \\
\sigma_e \cdot X_s & \text{if } e \notin I \text{ and } s \text{ is the largest stage with } A_s(e) = 0 \text{ and } \\
\sigma_e \cdot X & \text{if } e \notin I \text{ and } e \in A.
\end{cases}
\]

where \( \sigma_e \) is a string chosen when \( e \) is enumerated into the complement of \( I \) at some stage \( s \) such that \( \sigma_e \gtrdot_{\text{lex}} \alpha_{h(e),s} \). Each \( \beta_e \) is left-r.e. because \( h \) is recursive, the complement of \( I \) is r.e. and \( \gamma = \sup \gamma_s \). Furthermore, \( \beta \) is a \( K \)-acceptable numbering as the mapping \( n \mapsto i_n \) is \( K \)-recursive. For \( e \notin I \), \( \beta_e \in \mathcal{D} \) iff \( \beta_e \in \mathcal{C} \) iff \( e \in A \). As \( I \) is indifferent for \( A \) with respect to \( \mathcal{C} \), it follows that \( \{e : \beta_e \in \mathcal{D}\} \) is in \( \mathcal{C} \) and therefore also in \( \mathcal{D} \). So \( \mathcal{D} \) is made into itself by the universal left-r.e. numbering \( \beta \).

A set \( A \) is called **low** if \( A' \equiv_T K \) and \( A \) is called **high** if \( A' \geq_T K' \).

**Theorem 2.4.** For every low Martin-Löf random set \( A \), there exists a co-r.e. set which is indifferent for \( A \) with respect to the class of Martin-Löf random sets and retraceable by a recursive function.
Proof. Let $A$ be a low Martin-Löf random set, for example
\[ A = \{ x : 2x \in \Omega \} \tag{2.1} \]
is Martin-Löf random and low by van Lambalgen’s Theorem \cite{44} and \cite[Theorem 3.4]{14}, see also \cite[Theorem 3.4.1]{32}. Then
\[ f(n) = \max \{ m : H(A \upharpoonright m) \leq m + 3n \} \]
is partial-recursive in $A$ and hence $K$-recursive. By Lemma \cite{22}, there exists a co-r.e. set $I$ which is retraceable by a recursive function and satisfies
\[ f(n) < i_n < i_{n+1} \tag{2.2} \]
for all $n$. Let $k(m)$ be the number such that
\[ i_{k(m)} < m \leq i_{k(m)+1}, \]
and let $r(m)$ be the number such that
\[ f[r(m)] < m \leq f[r(m) + 1], \]
which exists by Miller and Yu’s Ample Excess Lemma \cite{31}, see \cite[Corollary 6.6.2]{15}. By (2.2) we have $k(m) \leq r(m)$ for all sufficiently large $m$; otherwise
\[ f[r(m) + 1] < i_{r(m)+1} \leq i_{k(m)} < m, \]
which is impossible.

Suppose that there were some Martin-Löf non-random set $N$ such that $N \triangle A \subseteq I$. We can code a prefix of the set $A$ given sufficiently long prefixes for $N$ and $I$, and so for infinitely many $m$
\[
H(A \upharpoonright m) \leq H(N \upharpoonright m) + H[A(i_0)A(i_1) \ldots A(i_{k(m)})] + 2 \log m + O(1) \\
< m + 2k(m) + 2 \log m + O(1) \\
\leq m + 2r(m) + 2 \log m + O(1).
\]
Here the additive log factor is used for coding two implicit programs into a single string. On the other hand, by the definition of $f$,
\[ H(A \upharpoonright m) > m + 3r(m) \]
for all $m$, a contradiction. Therefore $I$ is indifferent for $A$. \hfill $\Box$
We are now ready to prove that several classes can be made into themselves. Since left-r.e. Martin-Löf random sets exist \[12, 15\], the following result is immediate from Theorem 2.4 and Lemma 2.3.

**Corollary 2.5.** If a class \( C \) contains all Martin-Löf random sets and no recursive sets then \( C \) can be made into itself. In particular, the classes of Martin-Löf random sets, recursively random sets, Schnorr random sets, Kurtz random sets, bi-immune sets, immune sets, sets which are not strongly infinitely often autoreducible and nonrecursive sets can be made into themselves.

See the usual textbooks on recursion theory and algorithmic randomness for the definition of these notions \[15, 27, 32, 33, 38, 40\] and the paper of Arslanov \[2\] for the definition of the strongly infinite-often autoreducible sets. It is also straightforward to make non-random sets into themselves via an acceptable numbering: Just enumerate the left-r.e. sets on the even indices and one fixed member of the class on the odd indices. This numbering makes each class containing all non-immune sets (plus perhaps some others) have a non-immune index set.

We now investigate self reference for the class of 1-generic sets, a class of sets orthogonal to Martin-Löf random sets with respect to Baire category and measure. A set of binary strings \( A \) is called *dense* if for every string \( \sigma \) there exists \( \tau \in A \) extending \( \sigma \). A set is *weakly 1-generic* if it has a prefix in every dense r.e. sets of binary strings. Furthermore \( X \) is *1-generic* if for every (not necessarily dense) r.e. set of strings \( W \), either \( X \) has a prefix in \( W \) or some prefix of \( X \) has no extension in \( W \). Every 1-generic set is weakly 1-generic \[32\]. The following result isolates and generalises the main idea of \[21, \text{Theorem 23}\].

**Theorem 2.6.** Every \( K \)-recursive 1-generic set \( A \) has a co-r.e. indifferent set which is retraceable by a recursive function.

**Proof.** Let \( W_0, W_1, \ldots \) be any enumeration of the r.e. sets, and let \( R_e \) denote the \( e^{\text{th}} \) genericity requirement: \( \rho \) satisfies \( R_e \) if either some prefix of \( \rho \) belongs to \( W_e \) or no proper extension of \( \rho \) belongs to \( W_e \). First we show that there exists a \( K \)-recursive function \( f \) such that

\[
(\forall n) \ (\forall e \leq f(n)) \ (\forall \sigma \in \{0, 1\}^{f(n)}) \ 
[\sigma \cdot A[f(n)]A[f(n) + 1] \ldots A[f(n + 1)] \text{ satisfies } R_e].
\]
For any given $\sigma$ and $e$, there must be some sufficiently long segment of $A$, say $A(|\sigma|)A(|\sigma|+1)\ldots A(c_{\sigma,e})$, satisfying $R_e$ since $W_e$ is an r.e. set and $A$ is 1-generic. Now let $f(0) = 0$ and

$$f(n+1) = \max\{c_{\sigma,e} : |\sigma|, e \leq f(n)\}.$$ 

$f$ can be computed using an $A$ and a halting set oracle, hence $f$ is $K$-recursive. Now using Lemma 2.2 obtain a co-r.e. set $I$ which is retraceable by a recursive function and satisfies $i_n > f(2n)$ for all $n$. By the pigeonhole principle, for every $n$ there exist at least $n$ intervals below $f(2n)$ of the form

$$J_k = \{f(k)+1, f(k)+2, \ldots, f(k+1)\} \quad (k \leq 2n)$$

which do not contain a member of $I$. Hence $J_n \cap I = \emptyset$ for infinitely many $n$. For any $B$ satisfying $A\Delta B \subseteq I$, each such $n$ witnesses that some initial segment of $B$ satisfies $R_e$ for all $e \leq f(n)$, hence $I$ is indifferent for $A$ with respect to the class of 1-generic sequences.

While a left-r.e. set cannot be 1-generic [32], it can be weakly 1-generic [40]. This follows from the fact that a 1-generic set cannot compute a nonrecursive r.e. set [40]. Thus by Theorem 2.6 and Lemma 2.3 we obtain the following result.

**Corollary 2.7.** Any class of non-recursive sets containing the weakly 1-generic sets can be made into itself.

Day has thoroughly investigated indifferent sets for 1-generic sets [13]. He showed that every 1-generic set has an indifferent set which is itself 1-generic and also points out, as follows from Theorem 2.6, that every $K$-recursive 1-generic set has a co-r.e. indifferent set.

### 3. Things which cannot be made into themselves

In this section we show that there are many classes which cannot be made into themselves. The easiest example is the class of all finite sets as this class cannot have a finite index set.

**Theorem 3.1.** There is no left-r.e. numbering for the non-r.e. left-r.e. sets. Similarly, there is no left-r.e. numbering for the non-recursive left-r.e. sets.
Proof. Assume $\alpha_0, \alpha_1, \ldots$ is a recursive enumeration containing no cofinite set. It is now shown that there is also a non-r.e. left-r.e. set $B$ which differs from all $\alpha_e$. For this, let $F$ be the $K$-recursive function such that $F(e)$ is the maximum of the $e$-th non-elements in each of the sets $\alpha_0, \alpha_1, \ldots, \alpha_e$. One builds $B$ such that the complement of $B$ consists of elements $x_e = 2^e \cdot 3^{d(e)}$ where $d(e)$ is the supremum of all $F_s(e)$ for a recursive approximation $F_s$ to $F$; furthermore, whenever $x_e \notin W_{e,s} \wedge 3x_e \in W_{e,s}$ then $d(e)$ is incremented by 1. Note that the latter is done only once after $F(e)$ has converged and that the latter enforces that $W_e(x_e) \neq B(x_e) \lor W_e(3x_e) \neq B(3x_e)$ so that $B$ is not an r.e. set. It is easy to see that $B$ is a left-r.e. set; the reason is that the definition of $d(e)$ permits to make an approximation $x_{e,s}$ to $x_e$ monotonically from below and that therefore the approximation $B_s = \{y : \forall e [y \neq x_{e,s}]\}$ is a left-r.e. approximation to $B$. Hence $\alpha_0, \alpha_1, \ldots$ cannot be the numbering of all nonrecursive left-r.e. sets nor the numbering of all non-r.e. left-r.e. sets.

Although somewhat disappointing, the next fact follows as a consequence.

**Corollary 3.2.** The r.e. sets, co-r.e. sets and recursive sets cannot be made into themselves.

**Proof.** Suppose that $\alpha$ is a universal left-r.e. numbering which makes the r.e. sets into themselves, and say the $\alpha$-index set of the r.e. sets is $R$. Let $X$ be any set which is left-r.e. but not r.e., for example a left-r.e. Martin-Löf random. Now define a left-r.e. numbering $\beta$ by

$$
\beta_e = \begin{cases} 
\alpha_e & \text{if } e \notin R, \\
\sigma \cdot X & \text{for some finite } \sigma \text{ otherwise.}
\end{cases}
$$

In detail, $\beta_e$ follows the enumeration of $\alpha_e$ until $e$ gets enumerated into $R$ (if this ever happens), at which point $\beta$ switches to enumerating $X$. Thus $\beta$ is an enumeration of the non-r.e. left-r.e. sets, contrary to Theorem 3.1.

Now, suppose that some universal left-r.e. numbering $\gamma$ makes the co-r.e. sets into themselves. Let $Q$ be the $\gamma$-index set of the co-r.e. sets, and note that the class of left-r.e. co-r.e. sets is the class of left-r.e. recursive sets. By a construction analogous to the one for $\beta$ above, there exists a left-r.e. numbering consisting of the left-r.e. sets with $\gamma$-indices in $\overline{Q}$. This is an enumeration of all left-r.e. sets which are non-recursive, contradicting Theorem 3.1. Since $Q$ is also the index set of recursive sets, the recursive sets cannot be made into themselves either. 

\[ \square \]
Another example of what cannot be done is the following; the class of left-r.e. Martin-Löf random sets is quite natural and also known as the class of Ω-numbers \([9, 25, 30]\). The reason is that they can be represented as the halting probability of some universal prefix-free Turing machine.

**Proposition 3.3.** The left-r.e. Martin-Löf random sets cannot be made into themselves.

**Proof.** If the left-r.e. Martin-Löf random reals could be made into themselves, then the set of indices for Martin-Löf non-random reals would be \(\Delta_2\) inside this numbering. This contradicts a theorem of Kjos-Hanssen, Stephan, and Teutsch \([23]\) which says that the Martin-Löf non-randoms are never \(\Pi^0_3\) in any universal left-r.e. numbering.

We remark that any set that can be made into itself via an acceptable numbering contains an infinite recursive subset by the Padding Lemma \([33, 37]\). This means that the Martin-Löf randoms, the recursively random sets, the Schnorr randoms, the Kurtz randoms, the bi-immune sets, and immune sets cannot be made into themselves using an acceptable numbering. Figueira, Miller and Nies \([16]\) asked whether Chaitin’s Ω can have an infinite co-r.e. indifferent set. A partial solution to this problem follows immediately from the Lemma 2.3 and Proposition 3.3: if such a co-r.e. indifferent set exists, it cannot be retraceable by a recursive function.

In contrast to Proposition 3.3, every acceptable numbering of the left-r.e. reals makes the autoreducible reals into themselves as the resulting index set is a cylinder and thus autoreducible; the same applies for the notion of strongly infinitely-often autoreducible sets as cylinders have also that property. Note that not every set is autoreducible, for example Martin-Löf random reals fail to be autoreducible \([16, 42]\). By Corollary 2.5, the non-autoreducible reals can also be made into themselves, but by the above comment they cannot be made into themselves via an acceptable numbering.

4. Singleton classes

For the case of singletons, we can characterise which things can be made into themselves.

**Theorem 4.1.** A left-r.e. class \(\{A\}\) can be made into itself iff \(A \neq \emptyset\) and there exists an infinite, r.e. set \(B\) such that \(A \cap B = \emptyset\).
Proof. Assume $A$ can be made into itself via a universal left-r.e. numbering $\alpha$. Then $A \notin \{\emptyset, \omega\}$, so there exists a rational number $r$ with $A < r < 1$ where “$A$” is the set $A$ interpreted as a real number between 0 and 1. Let 

$$B = \{e : (\exists s)[\alpha_{e,s} > r]\}.$$ 

Then $A \cap B = \emptyset$, $B$ is r.e., and $B$ is infinite.

Conversely, assume $A \neq \emptyset$, and $B$ is an infinite r.e. set satisfying $A \cap B = \emptyset$. Then $B$ has an infinite recursive subset $R = \{b_0, b_1, \ldots\}$ Brodhead and Kjos-Hanssen [7] showed that there exists a Friedberg numbering, or enumeration without repetition, of the left-r.e. reals. Let $\alpha$ be a Friedberg numbering of the left-r.e. reals with the real $A$ deleted from the enumeration.

If $A$ is a finite set whose maximum element is $m$, then we can hardwire $A$ into the numbering $\gamma$ as follows:

$$\gamma_e = \begin{cases} 
A & \text{if } e \in A, \\
\emptyset & \text{if } e \notin A \text{ and } e < m, \\
\alpha_{e-(m+1)} & \text{if } e > m.
\end{cases}$$

Then $\gamma$ makes $A$ into itself. Now assume $A$ is infinite, and let $A_0, A_1, A_2, \ldots$ be a recursive approximation of $A$ from below where $A_n \neq A$ for all $n$. We then build a further numbering $\gamma$ such that

$$\gamma_e = \begin{cases} 
\alpha_d & \text{if } e = b_d, \\
A_s & \text{if } e \in A \cap \overline{R} \text{ and } s = \max\{t : e \in A_t\}, \\
A & \text{if } e \in A \cap \overline{R}.
\end{cases}$$

This $\gamma$ witnesses that $\{A\}$ can be made into itself. Moreover, $\gamma_e$ is left-r.e. via the following algorithm. Recursively decide whether the first case above is satisfied, and if it is not then $\gamma_e$ follows the left-r.e. approximation for $A$ whenever it appears that $e \in A$. \hfill \Box

In canonical universal left-r.e. numberings, no set gets made into itself.

**Proposition 4.2.** Let $\alpha$ be an acceptable universal left-r.e. numbering. Then for every set $B$, $\{e : \alpha_e = B\} \neq B$.

**Proof.** Every finite set has an infinite index set and is thus not made into itself. For every infinite set consider the left-r.e. numbering $\beta$ given by

$$\beta_e = B \cap \{x : (\exists y \in W_e)[x < y]\}.$$
Note that $\beta_e = B$ iff $W_e$ is infinite and that there is a recursive function $f$ with $\alpha_{f(e)} = \beta_e$ for all $e$. It follows that $W_e$ is infinite iff $\alpha_{f(e)} = B$. Hence $\{e : \alpha_e = B\}$ is not left-r.e. but rather $\Pi^0_2$-complete like the index set for the infinite sets [40].

5. Making things into themselves simultaneously

Having made certain classes into themselves and others not, we now investigate which collections of classes can be simultaneously made into themselves using a single numbering.

Definition 5.1. We say that $A$ and $B$ can be simultaneously made into themselves if there is a numbering which makes both $A$ into itself and $B$ into itself.

One thing we do not get at the same time is Martin-Löf random sets and weakly 1-generic sets. We showed in Corollary 2.5 and Corollary 2.7 that each of these classes can be made into themselves (by themselves), however their combination results in calamity.

Proposition 5.2. The Martin-Löf random sets and weakly 1-generic sets cannot simultaneously be made into themselves.

Proof. Assume that $\alpha$ makes the weakly 1-generic sets into themselves. Then the characteristic sequence for the $\alpha$-index set of the weakly 1-generic sets is itself weakly 1-generic and hence must contain very long runs of 1’s [32, Theorem 3.5.5]. On the other hand, no Martin-Löf random sets is weakly 1-generic [15, Proposition 8.11.9], and therefore the $\alpha$-index set for the Martin-Löf random sets must contain very long runs of 0’s. Thus it follows from [32, Theorem 3.5.21], which says that long runs of 0’s prevent a set from being Martin-Löf random, that the Martin-Löf random sets do not get made into themselves using $\alpha$. \hfill \qed

We note that for many classes which can be made into themselves and which have complementary classes which can also be made into themselves, the class and its complementary class cannot be simultaneously made into themselves.

Proposition 5.3. Any class closed under complements cannot be simultaneously made into itself with its complement.
Proof. Suppose that some class which is closed under complements can be made into itself. Then the indices for the complement in any universal left-r.e. numbering are also a member of the original class and hence do not belong to its complement.

Examples of important classes for which Proposition 5.3 applies include the Martin-Löf random sets and the autoreducible sets. Corollary 2.5 established that the Martin-Löf random sets can be made into themselves, and any acceptable universal left-r.e. numbering will make the non-Martin-Löf random sets into themselves via the Padding Lemma [40]. We established in the discussion following Proposition 3.3 that any acceptable universal left-r.e. numbering also makes the autoreducible sets into themselves. Hence the following corollary holds.

**Corollary 5.4.** The class of all sets which are not Martin-Löf random and the class of all autoreducible sets are simultaneously made into themselves by any acceptable universal left-r.e. numbering.

### 6. Minimal and maximal left-r.e. sets

A coinfinite r.e. set $A$ is called **maximal** [18] if there is no coinfinite r.e. superset $E \supset A$ with $E - A$ being infinite; in other words, an r.e. set $A$ is maximal iff $A \subset^* \mathbb{N}$ and there is no r.e. set $E$ with $A \subset^* E \subset^* \mathbb{N}$. The corresponding notion of minimal r.e. sets does not exist. Indeed, every infinite r.e. set $A$ contains an infinite recursive subset, and one can recursively remove every other element from this infinite recursive set to obtain an infinite r.e. subset of $A$ with infinitely fewer elements.

To what extent does the inclusion structure for the left-r.e. sets resemble that of the r.e. sets? One difference between these two structures is immediate. Unlike the situation for r.e. sets, intersections and unions of left-r.e. sets need not be left-r.e.; only the join

$$E \oplus F = \{2x : x \in E\} \cup \{2y + 1 : y \in F\}$$

of left-r.e. sets $E$ and $F$ is always left-r.e. For example, $\Omega$ intersected with the set of even numbers, call this set $A$, is not a left-r.e. set. If it were, then one could use this set to build a left-r.e. approximation for the set $B = \{x : 2x \in \Omega\}$ by updating at each stage those $B$-indices $e$ for which every odd $A$-index below $2e$ shows a zero. But, as established in (2.1), $B$
is low and Martin-Löf random, contradicting that every left-r.e. Martin-Löf random is an Ω-number \[9, 25, 30\] and that every Ω-number is weak-truth-table equivalent to, and hence Turing equivalent to, the halting problem \[11\]. An analogous construction shows that left-r.e. sets are not closed under inclusion.

**Definition 6.1.** A left-r.e. set \(A\) is called a **minimal left-r.e. set** iff \(\emptyset \subset A^*\) and there is no left-r.e. set \(E\) with \(\emptyset \subset E^* \subset A^*\). A left-r.e. set \(B\) is called a **maximal left-r.e. set** iff \(B \subset N^*\) and there is no left-r.e. set \(E\) with \(B \subset E^* \subset N^*\).

The next result shows that both types of sets exist, in contrast to the r.e. case where only maximal sets exist. Neither maximal left-r.e. sets, nor minimal left-r.e. sets, nor their respective complements need be hyperimmune (in contrast to the complements of maximal r.e. sets \[33\], Proposition III.4.14).

**Theorem 6.2.** There are a minimal set \(A\) and a maximal set \(B\) in the partially ordered structure of all left-r.e. sets and \(\subset^*\).

**Proof.** Let \(\Omega\) be Chaitin’s Martin-Löf random set and let \(\Omega_s\) be a left-r.e. approximation to it. Furthermore, let

\[
c_{n,s} = \sum_{m<2^n} 2^{2^n-m} \Omega_s(m)
\]

and \(c_n = \lim_{s \to \infty} c_{n,s}\). Let \(d_n = c_n - 2^{2^n-1}c_{n-1}\) so that \(d_n\) is the sum of all \(2^{2^n-m}\Omega(m)\) with \(m = 2^{n-1}, 2^{n-1+1}, \ldots, 2^n - 1\). Note that \(c_n \leq 2^n\) for all \(n\). Let \(I_1, I_2, \ldots\) be a recursive partition of \(N\) into intervals such that each interval \(I_n\) contains all numbers \(\langle n, x, y \rangle = \min(I_n) + x \cdot 2^{2^n} + y\) with \(x, y \in \{0, 1, \ldots, 2^{2^n} - 1\}\). Now let

\[
a_n = \langle n, c_{n-1}, 2^{2^n} - 1 - d_n \rangle \text{ for } n > 0,
\]

\[
b_n = g(a_n) \text{ where }
\]

\[
g(u) = \max(I_n) + \min(I_n) - u \text{ for all } n \text{ and all } u \in I_n,
\]

\[
A = \{a_1, a_2, \ldots\} \text{ and } B = N - \{b_1, b_2, \ldots\}.
\]

So \(g\) is defined such that if \(u\) is the \(r\)th smallest element of \(I_n\) then \(g(u)\) is the \(r\)th largest element of \(I_n\). Note that \(A\) and \(B\) are btt-equivalent: \(u \in A \iff g(u) \notin B\). Now it is shown that \(A\) is a minimal left-r.e. set and \(B\) is a maximal left-r.e. set.
The set $A$ is left-r.e. as one can start the enumeration at $s_0$ with $c_{0,s} = c_0$ and letting, for $s \geq s_0$, $A_s = \{a_{1,s}, a_{2,s}, \ldots, a_{s,s}\}$. Then one has for each $s \geq s_0$ that whenever there is an $n$ with $a_{n,s+1} > a_{n,s}$ then there is also a least $m \leq n$ where $a_{m,s+1} \neq a_{m,s}$ and it follows that for this number the change is in the $d$-part of $a_{m,s} = \langle m, c_{m-1,s}, 2^{2m} - 1 - d_{m,s} \rangle$ so that $a_{m,s+1} < a_{m,s}$. Hence it holds that $A_s \subseteq_{\text{lex}} A_{s+1}$ and the approximation of the $A_s$ is an left-r.e. approximation. Furthermore, let $B_s = (I_1 - \{b_{1,s}\}) \cup (I_2 - \{b_{2,s}\}) \cup \ldots \cup (I_s - \{b_{s,s}\})$. Note that $g$ inverts the direction of the approximation in the intervals. Hence, if $s \geq s_0$ and $b_{n,s+1} \neq b_{n,s}$ then the least $m \leq n$ with $b_{m,s+1} \neq b_{m,s}$ satisfies that $b_{m,s+1} > b_{m,s}$. Hence one can see that for $s \geq s_0$ it holds that $B_s \subseteq_{\text{lex}} B_{s+1}$ and $\lim B_s = B$.

Assume now that $E$ is an infinite left-r.e. subset of $A$ and let $E_s$ be a left-r.e. approximation of $E$. For any $n$ where $a_{n+1} \notin E$ and $a_{n+2} \in E$, let $\sigma$ be an $n$-bit binary string telling which of the first $n$ elements $a_1, \ldots, a_n$ is in $E$ and let $\psi(\sigma, c_n)$ be a partial-recursive function identifying the first stage $s \geq s_0$ such that $a_{1,s} = a_1, a_{2,s} = a_2, \ldots, a_{n,s} = a_n$ and

$$E_s \cap J_{n+2} = \{a_{m,s} : m \in \{1, 2, \ldots, n\} \land \sigma(m) = 1\} \cup \{a_{n+2,s}\};$$

where $J_n = I_1 \cup I_2 \cup \ldots \cup I_n$. Note that $n, a_1, \ldots, a_n$ can all be computed from $c_n$. Now, due to $E_s \subseteq_{\text{lex}} E$, the final value of $a_{n+2,s}$ cannot exceed $a_{n+2,s}$ for the chosen $s$, hence $c_{n+1,s} = c_{n+1}$. This implies that for all the $n$ where $a_{n+1} \notin E \land a_{n+2} \in E$ it holds that the Kolmogorov complexity of $c_{n+1}$ given $c_n$ is at most $n$ bits plus a constant; however, the prefix-free Kolmogorov complexity of each $c_n$ is approximately $2^n$ and therefore there can only be finitely many such $n$. It follows that almost all $a_n$ are in $E$. This shows that $A$ is a minimal left-r.e. set.

To see that $B$ is maximal, consider any coinfinite left-r.e. set $E$ containing $B$. As before one computes for each $n$ with $b_{n+1} \in E \land b_{n+2} \notin E$ and $\sigma$ being an $n$-bit string telling which of $b_1, b_2, \ldots, b_n$ are in $E$ the stage $\psi(c_n, \sigma)$ as the first stage $s \geq s_0$ such that $b_{1,s} = b_1, b_{2,s} = b_2, \ldots, b_{n,s} = b_n$ and

$$E_s \cap J_{n+2} = J_{n+2} - \{b_{m,s} : m \in \{1, 2, \ldots, n\} \land \sigma(m) = 0\} - \{b_{n+2,s}\}.$$ 

Note again that $n, b_1, b_2, \ldots, b_n$ can be computed from $c_n$. Now the $s = \psi(c_n, \sigma)$ satisfies that $b_{n+2,s} \leq b_{n+2}$ and hence $c_{n+1,s} = c_{n+1}$. This permits again to conclude by the same Kolmogorov complexity arguments as in the case of the set $A$ that $E$ is the union of $B$ and a finite set; hence $B$ is a maximal left-r.e. set. \qed
One might ask why we construct a maximal left-r.e. set instead of checking whether some maximal r.e. set is also maximal as a left-r.e. set. Unfortunately this approach does not work, as the following result shows.

**Theorem 6.3.** No r.e. set can be a maximal left-r.e. set.

**Proof.** Let $A$ be an infinite r.e. set. Without loss of generality assume that exactly one new element gets enumerated into $A$ at each stage of its recursive approximation $A_0, A_1, A_2, \ldots$ and for each $s$, let $x_0, x_1, x_2, \ldots$ denote the complement of $A_s$ in ascending order and define

$$E_s = A_s \cup \{x_1, x_3, x_5, \ldots\}.$$ 

Now assume that there is a stage $s$ and $x_n \in A_{s+1} - A_s$ being the unique element enumerated into $A$ at stage $s$. If $n$ is even, then

$$E_{s+1} = E_s \cup \{x_n, x_{n+2}, x_{n+4}, \ldots\} - \{x_{n+1}, x_{n+3}, \ldots\},$$

and if $n$ is odd, then

$$E_{s+1} = E_s \cup \{x_{n+1}, x_{n+3}, \ldots\} - \{x_{n+2}, x_{n+4}, \ldots\}.$$ 

In either case the minimum of the symmetric difference of $E_s$ and $E_{s+1}$, which is $x_n$ when $n$ is even and $x_{n+1}$ when $n$ is odd, belongs to $E_{s+1}$. Hence $E_s \leq \text{lex} E_{s+1}$. The left-r.e. set $E = \lim E_s$ contains all elements of $A$ and every second element of the complement of $A$, hence $A$ is not maximal in the structure of the left-r.e. sets under inclusion. □

A further interesting question is the following: For maximal r.e. sets $C$ one has the property that there is no r.e. set $E$ with $E - C$ and $\overline{E} - C$ being infinite [40, p. 187]. Do the corresponding properties also hold for minimal and maximal left-r.e. sets? That is, can one make sure that no left-r.e. set splits a minimal left-r.e. set $A$ into two infinite parts or the complement of a maximal left-r.e. set $B$ into two infinite parts? The answer is “no”.

**Theorem 6.4.** Let $A$ be an infinite left-r.e. set and $B$ be a coinfinite left-r.e. set. Then there is an infinite left-r.e. set $E$ such that $A \cap E$ and $A \cap \overline{E}$ are both infinite. Furthermore there is an infinite left-r.e. set $F$ such that $\overline{B} \cap F$ and $\overline{B} \cap \overline{F}$ are both infinite.
Proof. Assume by way of contradiction that $A$ and $B$ exist. Then the set of even number neither splits $A$ nor the complement of $B$ into two infinite halves; therefore without loss of generality, all members of $A$ are odd and all non-members of $B$ are odd.

Let $A = \{a_0, a_1, a_2, \ldots\}$ and $\overline{B} = \{b_0, b_1, b_2, \ldots\}$ be denoted such that $a_k < a_{k+1}$ and $b_k < b_{k+1}$ for all $k$. Now choose $E$ and $F$ such that

$$E = \{a_{2k}, a_{2k+1} - 1 : k \in \mathbb{N}\} \quad \text{and} \quad \overline{F} = \{b_{2k}, b_{2k+1} - 1 : k \in \mathbb{N}\}.$$ 

One can obtain corresponding approximations $E_s$ and $F_s$ for $E$ and $F$, respectively, by using analogous formulas to define $E_s$ from $A_s$ and $\overline{F}_s$ from $\overline{B}$. Fix left-r.e. approximations $A_s$ to $A$ with $A_s(2x) = 0$ for all $x$ and $B_s$ to $B$ with $B_s(2x) = 1$ for all $x$. Then $A_s \leq \text{lex} A_{s+1} \Rightarrow E_s \leq \text{lex} E_{s+1}$ and $B_s \leq \text{lex} B_{s+1} \Rightarrow F_s \leq \text{lex} F_{s+1}$. Hence both sets $E$ and $F$ are left-r.e. sets. Furthermore, $A \cap E = \{a_0, a_2, a_4, \ldots\}$, $A \cap \overline{E} = \{a_1, a_3, a_5, \ldots\}$, $\overline{B} \cap F = \{b_1, b_3, b_5, \ldots\}$ and $\overline{B} \cap \overline{F} = \{b_0, b_2, b_4, \ldots\}$. Hence $E$ and $F$ meet the requirements.

Having established the fundamentals on minimal and maximal left-r.e. sets, the time is ready for the question which of them can be made into themselves.

**Theorem 6.5.** There is a minimal left-r.e. set $A$ such that $\{A\}$ can be made into itself. There is no maximal left-r.e. set $B$ such that $\{B\}$ can be made into itself.

Proof. One can easily see that the intervals $I_n$ in Theorem 6.2 can be chosen large enough so that $a_n \neq \max(I_n)$ for all $n$; hence $A = \{a_0, a_1, \ldots\}$ is disjoint from an infinite recursive set and so $\{A\}$ can be made into itself by Theorem 4.1.

Assume now that $B$ is a maximal left-r.e. set; one has to show that there is no infinite recursive set $R$ disjoint from $B$. Assume the contrary and without loss of generality $R \cup B$ is coinfinite (otherwise $B$ is the complement of a recursive set and not maximal). Let $B_0, B_1, \ldots$ be a left-r.e. approximation of $B$. Now one can select a sequence $s_0, s_1, \ldots$ of stages such that $B_{s_t} \cap \{0, 1, \ldots, t\}$ is disjoint from $R$. Hence $E_t = (B_{s_t} \cap \{0, 1, \ldots, t\}) \cup R$ is a recursive left-r.e. approximation of $B \cup R$ which then witnesses that $B$ was not, as assumed, a maximal left-r.e. set. Hence there is no infinite recursive set disjoint to $B$ and, by Theorem 4.1, $\{B\}$ cannot be made into itself. \qed
The next result shows that each of the classes of minimal left-r.e. sets and maximal left-r.e. sets cannot be made into itself; the proof method is to show that the corresponding index-sets cannot be $K'$-recursive and therefore cannot be left-r.e., let alone minimal or maximal.

**Theorem 6.6.** Neither the class of minimal left-r.e. sets nor the class of maximal left-r.e. sets can be made into itself.

**Proof.** Let $A$ be the minimal and $B$ be the maximal left-r.e. set from Theorem 6.2. Recall that $I_1, I_2, \ldots$ is a recursive partition of the natural numbers such that $A$ has exactly one element in $I_n$ for each $n$. Let $\text{ind}(x) = n$ for the unique $n$ with $x \in I_n$; the function $\text{ind}$ is recursive. We show that with respect to any universal left-r.e. numbering $\alpha$, neither the minimal nor the maximal left-r.e. sets can be made into itself.

Let $P$ be the index set of the minimal left-r.e. sets in $\alpha$. Now consider for any r.e. set $W_e$ the set $\tilde{A}_e$ given as

$$\{3x : x \in A \land \text{ind}(x) \in W_e\} \cup \{3x + 1, 3x + 2 : x \in A \land \text{ind}(x) \not\in W_e\}.$$ 

One can easily see that $\tilde{A}_e$ has a left-r.e. approximation; starting with a left-r.e. approximation $A_s$ for $A$ and an enumeration $W_{e,s}$ for $W_e$, the approximation $\tilde{A}_{e,s}$ is the same as for $\tilde{A}_e$ except $A$ is replaced with $A_s$ and $W_e$ is replaced with $W_{e,s}$.

If $W_e$ is cofinite then the set $\tilde{A}_e$ is a finite variant of $\{3x : x \in A\}$ and thus minimal; if $W_e$ is coinfinite then the set $\tilde{A}_e$ has an infinite left-r.e. subset which has infinitely many less elements than $\tilde{A}_e$, namely

$$\{3x : x \in A \land \text{ind}(x) \in W_e\} \cup \{3x + 1 : x \in A \land \text{ind}(x) \not\in W_e\}.$$ 

There is a $K'$-recursive mapping which determines for every $e$ the least index $d$ with $\alpha_d = \tilde{A}_e$; now $d \in P$ iff $W_e$ is cofinite. As the set $\{e : W_e \text{ is cofinite}\}$ is not $K'$-recursive in any acceptable numbering of the r.e. sets [40, Corollary IV.3.5], $P$ cannot be $K'$-recursive and therefore is not a minimal left-r.e. set.

Now let $Q$ be the index set of the maximal left-r.e. sets in the given enumeration $\alpha$. Recall that $B$ is a fixed maximal left-r.e. set. Now each join $B \oplus W_e$ is left-r.e. and is a maximal left-r.e. set iff $W_e$ is cofinite. Again there is a $K'$-recursive mapping which finds for each $e$ an index $d$ with $B \oplus W_e = \alpha_d$; hence one can, relative to $K'$, many-one reduce the index set of the cofinite sets to $Q$. As the index set of the cofinite sets is not $K'$-recursive, $Q$ also cannot be $K'$-recursive; hence $Q$ cannot be left-r.e. and in particular is not a maximal left-r.e. set. 

\[\square\]
We now turn our attention to the question of which things can be directly stuck inside other things. Kummer [26] showed that there exists a numbering $\varphi$ of the partial recursive sets such that the r.e. inclusion problem,

$$\text{INC}_{\varphi} = \{ \langle i, j \rangle : W_i^{\varphi} \subseteq W_j^{\varphi} \},$$

is recursive in the halting set and asked whether there exists a numbering $\varphi$ of the partial recursive sets such that $\text{INC}_{\varphi}$ is r.e. Kummer’s question remains open, however in the context of left-r.e. sets we show the answer is negative. Below we use $\text{INC}_\alpha$ to denote the left-r.e. inclusion problem.

**Theorem 7.1.** For every universal left-r.e. numbering $\alpha$,

1. $\text{INC}_\alpha$ is not r.e. and
2. $\text{INC}_\alpha \geq_T K$.

**Proof.** For part (i), define the following two sets:

$$A = \text{the set of odd numbers,}$$

$$B = \{2x : x \in K\} \cup \{2x + 1 : x \notin K\}.$$ 

Note that $A \cap B = \{2x + 1 : x \notin K\}$ and that $A$ and $B$ are both left-r.e.: the characteristic function of $B$ on $2x, 2x + 1$ changes from 01 to 10 whenever $x$ goes into $K$, hence this is a left-r.e. process.

Let $\alpha$ be a universal left-r.e. numbering and suppose that $\text{INC}_\alpha$ were r.e. For each number $x$, we show how to decide membership in the set $\{y \in K : y < x\}$. We search for a left-r.e. set $E$ and a number $s$ such that the following has happened up to stage $s$:

- The indices for $E \subseteq A$ and $E \subseteq B$ have both been enumerated into the inclusion problem;
- for all $y < x$, either $y \in K$ or $2y + 1 \in E_s$ but not both.

Note that $E$ cannot acquire any further element $2z + 1 < 2x$ after stage $s$ as then $2z + 1 \in B$ which implies $z \notin K$, contrary to the second item above. Hence $E$ does not change below $2x$ after stage $s$ and therefore one knows for all $y < x$ that $y \in K$ iff $y \in E_s$. An $\alpha$-index for such a set $E$ exists as
every finite set has an index in $\alpha$, and therefore our search terminates. The recursive algorithm just described thus decides the halting problem, which is impossible.

For part (ii), note that instead of searching for enumerations of the inclusion problem, one can run the above algorithm relative to the inclusion problem and so show that $K$ is Turing reducible to the inclusion problem with that algorithm. \qed

We leave the following open questions for the left-r.e. inclusion problem:

**Question 7.2.** Does there exist a numbering $\alpha$ for the left-r.e. sets such that $\text{INC}_\alpha \equiv_T K$? In particular, can we make $\text{INC}_\alpha$ to be left-r.e.?

Consider the related relation

$$\text{LEX}_\alpha = \{ \langle i, j \rangle : \alpha_i \leq_{\text{lex}} \alpha_j \}.$$ 

Any Friedberg numbering $\alpha$ makes $\text{LEX}_\alpha$ recursive in the halting set. The reason is that no two distinct indices in a Friedberg numbering represent the same left-r.e. set, so a halting set oracle suffices to find a sufficiently long prefix which reveals the lexicographical order of the strings. We can improve this result to a numbering such that the left-r.e. relation itself becomes left-r.e.

**Theorem 7.3.** There exists a universal left-r.e. numbering $\alpha$ such that $\text{LEX}_\alpha$ is an r.e. relation.

**Proof.** Let $\beta$ be a Friedberg left-r.e. numbering which includes indices for all the left-r.e. sets except for $\mathbb{N}$. We define a universal left-r.e. numbering $\alpha$ based on $\beta$ as follows. Informally, during the first $s$ stages, $\alpha$ follows the first $s$ indices of $\beta$ for $s$ computation steps, and some finitely many other $\alpha$-indices $e$ have been defined to be $\alpha_e = \mathbb{N}$. If $\alpha_e = \mathbb{N}$, we say that the index $e$ has been obliterated. We describe stage $s + 1$. For each pair $\langle i, j \rangle$ with $i < j$ where $\beta_i$ becomes lexicographically larger than $\beta_j$ at stage $s + 1$, that is, $\beta_{i,s} \leq_{\text{lex}} \beta_{j,s}$ but $\beta_{i,s+1} >_{\text{lex}} \beta_{j,s+1}$, the index for the $\alpha$-follower of $\beta_j$ and all larger defined $\alpha$-indices are obliterated and a new $\alpha$-follower for $\beta_j$ and each of the other newly obliterated indices is established. Also in stage $s + 1$, an $\alpha$-follower for $\beta_{s+1}$ is established so that in the end each $\beta$-index will have a unique $\alpha$-index following it. Note that only finitely many $\alpha$-indices are defined in any given stage.
For every $e$, the $\alpha$-index following $\beta_e$ eventually converges once sufficiently much time has passed to allow the approximation of $\beta_e$’s prefix to differ from the approximation of every lesser $\beta$-index’s prefix and also enough time that these prefixes never again change. Furthermore, obliterating indices can only ever increase membership of the respective set, so $\alpha$ is a universal left-r.e. numbering. Finally, $\alpha$ is r.e. because whenever $\beta$’s enumeration tries to push $\langle i, j \rangle$ out of LEX$_\alpha$, the index $j$ gets obliterated and hence $\langle i, j \rangle$ stays inside LEX$_\alpha$.

\[ \square \]

**Summaries**

关于可以成为自己一员的性质. 我们说一个自然数的性质$P$可以成为自己的一员，指的是所有左递归集有一个编码使得满足性质$P$的指标集也具有性质$P$。例如，Martin-Löf随机性质就可以变成自己的一员。在此，我们刻画所有可以成为自己一员的单元集性质。我们接着研究，有限同余情况下，左递归集所组成的类在包含关系下的结构。这种结构不仅有极大元而且有极小元。相比而言，相应的递归集所组成的类只有极大元没有极小元。而且，我们构造左递归集的极大元和极小元的方法与经典的Friedberg关于递归类的极大元的方法有很大不同。最后，本文研究极大和极小左递归集的性质是否可以变成自己的一员。

**Ajoj kiojn oni povas meti en si mem.** Ar $A$ estas rekursive enumerabla se $A$ estas la limo de uniforme rekursivaj aroj $A_0, A_1, \ldots$ je kiu $A_n \subseteq A_{n+1}$ por ĉiu $n$; $A$ estas maldekstre rekursive enumerabla se $A$ estas la limo de uniforme rekursivaj aroj $A_0, A_1, \ldots$ je kiu $A_n \leq_{lex} A_{n+1}$ por ĉiu $n$. La publikajo temas pri la sekvanta afero: Se $\alpha_0, \alpha_1, \ldots$ estas numerado da maldekstre rekursive enumerabla aroj kaj se $P$ estas abstrakta eco de aroj (kiel esti Martin-Löf hazarda), tiam oni konsideru la indeksa aro $\{ e : \alpha_e \text{ havas econ } P \}$. Oni diras ke oni povas meti la $P$ en si mem se ekzistas numerado $\alpha_0, \alpha_1, \ldots$ de ĉiu maldekstre rekursive enumerabla aroj tiel ke la indeksa aro por $P$ je tiu numerado ankaŭ havas la econ $P$. En tiu-ĉi publikajo estas diversaj teoremoj kiu diras ke multaj famaj ecoj el teorio pri rekursivaj funkcioj kaj algoritnika hazardo se oni povas meti tiujn ecojn en si mem. Ekzemple, oni povas meti la Martin-Löf hazarda arojn en si mem. Plue, se la aro $A$ havas minimume unu membro kaj estas maldekstre rekursive enumerabla, tiam oni povas meti la econ $P(X)$ dirante $X = A$ en si mem ekzakte se ekzistas malfinia rekursive enumerabla aro $B$ kiu havas malplenajn komunajn kun $A$. Oni ankaŭ esploras pri minimumaj kaj maksimumaj aroj en la strukturo de maldekstre rekursive enumerabla aroj je la ordo $\subseteq^*$. Kvankam en la
mondo de rekursive enumerablaj aroj la minimuma aroj ne ekzistas, ambaŭ ekzistas en la mondo de maldekstre rekursive enumerablaj aroj kaj la pruvo malsimilas al tiu de Friedberg por la mondo de rekursive enumerablaj aroj.

**Dinge die in sich selbst gemacht werden können.** Eine Menge $A$ natürlicher Zahlen heisst rekursiv aufzählbar (r.a.) genau dann wenn es eine uniform-rekursive Folge $A_0, A_1, \ldots$ gibt welche punktweise gegen $A$ konvergiert und $A_n \subseteq A_{n+1}$ für alle $n$ erfüllt; $A$ heisst links-r.a. genau dann wenn es eine uniform-rekursive Folge $A_0, A_1, \ldots$ gibt welche punktweise gegen $A$ konvergiert und $A_n \leq_{lex} A_{n+1}$ für alle $n$ erfüllt. Das Thema der Arbeit ist der folgende Selbstbezug: Man sagt dass eine Eigenschaft $P$ von Mengen natürlicher Zahlen in sich selbst gemacht werden kann wenn es eine Numerierung $\alpha_0, \alpha_1, \ldots$ aller links-r.a. Mengen gibt so dass die Index-Menge \{e : $\alpha_e$ hat die Eingenschaft $P$\} ebenfalls die Eigenschaft $P$ hat. Es wird untersucht, welche bekannten rekursions-theoretischen Eigenschaften diese Art von Selbstbezug haben, zum Beispiel hat die Eigenschaft “Martin-Löf zufällig” einen solchen Selbstbezug. Man kann auch die Eigenschaft $P$ betrachten wo $P(X)$ bedeutet dass $X = A$ ist für eine feste gegebene nichtleere links-r.a. Menge $A$. Nun hat $P$ die obenerwähnte Art von Selbstbezug genau dann wenn $A$ zu einer unendlichen rekursiv aufzählbaren Menge $B$ disjunkt ist. Desweiteren wurde die Struktur der links-r.a. Mengen mit der partiellen Ordnung $\subseteq^*$ untersucht. Es wird gezeigt dass es in dieser Struktur, anders als im Fall der r.a. Mengen, nicht nur maximale sondern auch minimale links-r.a. Mengen gibt; die Konstruktion ist recht unterschiedlich von der Konstruktion welche Friedberg im r.a. Fall benutzte. Desweiteren werden die Selbstbezugs-eigenschaften von minimalen und maximalen links-r.a. Mengen untersucht.
