End-Triassic mass extinction started by intrusive CAMP activity

J.H.F.L. Davies¹, A. Marzoli², H. Bertrand³, N. Youbi⁴,⁵, M. Ernesto⁶ & U. Schaltegger¹

The end-Triassic extinction is one of the Phanerozoic's largest mass extinctions. This extinction is typically attributed to climate change associated with degassing of basalt flows from the central Atlantic magmatic province (CAMP). However, recent work suggests that the earliest known CAMP basalts occur above the extinction horizon and that climatic and biotic changes began before the earliest known CAMP eruptions. Here we present new high-precision U-Pb ages from CAMP mafic intrusive units, showing that magmatic activity was occurring ~100 Kyr ago before the earliest known eruptions. We correlate the early magmatic activity with the onset of changes to the climatic and biotic records. We also report ages from sills in an organic rich sedimentary basin in Brazil that intrude synchronously with the extinction suggesting that degassing of these organics contributed to the climate change which drove the extinction. Our results indicate that the intrusive record from large igneous provinces may be more important for linking to mass extinctions than the eruptive record.
The central Atlantic magmatic province (CAMP) is one of the world’s most expansive large igneous provinces (LIP) with an estimated areal extent of ca. 10^7 km^2. The province was emplaced as mafic dykes, sills, layered intrusives and basalt flows in rift basins of the Pangean supercontinent at ~201 Ma (Fig. 1; refs 1–4). High-precision U-Pb geochronology of the CAMP basalts in eastern North America and Morocco has temporally linked the onset of CAMP with the end-Triassic mass extinction (ETE) as determined by zircon U-Pb geochronology from ashes bracketing the extinction interval in Peru. The ETE, the third largest of the Phanerozoic extinctions, is identified in the marine record by the loss of Triassic ammonites and devastation to the scleractinian corals. In the continental record it is recognized by a turnover in sporomorphs and early Mesozoic vertebrates as well as a >95% turnover of megaflora. The ETE is also associated with a global ~3–6‰ negative carbon isotope excursion, which is recorded in both the marine and terrestrial records allowing the two records to be correlated. Geochronologically, the age for the carbon isotope excursion from the marine and continental records overlap, however, there is still some controversy over whether the carbon isotope excursion in the orbitally tuned strata of the Newark basin really marks the extinction.

During the extinction period, atmospheric CO₂ concentrations were thought to have increased up to four times the pre-extinction levels creating up to 3–4 °C of warming. Increased atmospheric pCO₂ concentrations are indicative of ocean acidification suggesting that this may have been a marine event.
extinction mechanism especially in relation to the scleractinian corals. The temporal relationship between the CAMP and the ETE has led to the speculation that CAMP magmatism played a major role in the climate change and associated mass extinction. However, recent detailed carbon isotope stratigraphy on the sediments underlying the earliest known CAMP basalts in Morocco and North America has revealed that the flows were emplaced above the carbon isotope excursion marking the extinction horizon, questioning the causality of the link between the two.

Indirect evidence for CAMP activity before the earliest basalts has been discovered in different locations worldwide, for example, the identification of seismites below the ETE horizon in northern Europe, which have been interpreted as resulting from movement of magmas (presumed to be CAMP related) at depth. Sediments from weathered mafic rocks are present below the first basalt flows in Morocco, which is interpreted as evidence for undiscovered basalts below the ETE. Also, global sea level regression record in the Rhetian sediments of UK, USA and Austria, which has been interpreted as evidence for climatic cooling associated with early degassing of sulfur from CAMP magmas at depth. Climatic change has also been suggested as an explanation for photic zone euxinia and increased ocean stratification in the northern Panthalassic Ocean before the ETE, as well as a loss of taxonomic richness in the bivalve and terrestrial vegetation records. Currently, there is no direct evidence for CAMP activity before the earliest basalts, and coincident with or before the carbon isotope excursion that marks the ETE, therefore the link between the ETE and the eruption of CAMP basalts remains speculative.

The ETE is defined in the marine realm by a turnover in ammonite species and also by a marked negative carbon isotopic excursion. This excursion has also been identified in the continental record in sediments at the base of the CAMP lava flows in the Argana basin and Central High Atlas of Morocco and the Canadian Fundy basin in North America. High precision geochronology from ashes bracketing the extinction interval and carbon isotope excursion in the marine record produces an age for the Triassic–Jurassic boundary of 201.36 ± 0.17 Myr and for the carbon isotopic shift marking the main phase of extinction of 201.51 ± 0.15 Myr ago (from ref. 5 recalculated by ref. 22). The age for the terrestrial ETE was calculated for the Newark basin as follows. First, the intrusion of the Palisades sill (dated at 201.520 ± 0.034 Ma) was assumed to belong to the same magma system as the Orange Mountain basaltic flow. This flow occurs ~20 m above a relatively modest carbon isotope excursion and a biologic turnover in the Newark basin, which has been interpreted to mark the extinction horizon. Considering that the sediments in the Newark basin have been orbitally tuned and that the 20 m of sedimentary strata should correspond to a precession cycle, assuming no hiatus in sedimentary deposition, the age for the ETE in the Newark basin is 201.564 ± 0.015 Myr from ref. 1. This continental ETE age overlaps with the age for the extinction in the marine record.

However, despite the age overlap between the marine and terrestrial records, the biostratigraphic definition of the ETE in continental basins is strongly debated. In particular, the definition of the ETE in the Newark basins is based on a pollen and spore turnover that is questioned by other palynologic and paleontological studies. Further confusing the continental record, there are suggestions that there may be a hiatus in sedimentation under the Orange Mountain basalt in the Newark basin (e.g. refs 2,22,27–29), which would invalidate the orbitally tuned age for the ETE. Above the Orange Mountain basalt, the floating chronology from the astronomically tuned Newark sediments matches well with the U-Pb ages suggesting a continuous sedimentary sequence above the basalts. Since the ages for the extinction horizon overlap between the marine and continental records we cautiously use the age of 201.564 Myr as an estimate of the age of the extinction, and acknowledge that this exact age may be refined in the future by further work in other continental basins straddling the end Triassic extinction.

Our new dates conclusively show, for the first time, that mafic magmatic activity associated with the CAMP was occurring ~100 kyr before the eruption of the previously dated Moroccan and North American basalts. We also show that shallow sills in the ~1,000,000 km² organic-rich Amazonas sedimentary basin of Brazil intrude simultaneously with the extinction, suggesting that degassing from organics in this basin may have contributed to the climatic impact of the CAMP, and consequently the ETE.

Results

U-Pb geochronology. Here we present high precision U-Pb ages for zircon (ZrSiO₄) and baddeleyite (ZrO₂) from mafic intrusive rocks over four continents in eight locations throughout the CAMP (Fig. 1) to better understand the relationship between the CAMP and the ETE and to search for a possible CAMP pre-eruptive history (at least in relation to the exposed sections in North America and Morocco). The relative timing of CAMP magmas has traditionally been determined by comparison with the geochemical signatures of the Moroccan basalt flows. However, the geochemical chronology breaks down when considering the intrusive units that we targeted in this study (Supplementary Fig. 3). Intrusive rocks were chosen in order to circumvent problems associated with stratigraphic correlations between the marine record and the two continental records in Morocco and North America. All of the samples have been previously characterized geochemically and shown to be part of the CAMP (Supplementary Information), we also provide Hf isotope data from the dated minerals to reinforce the geochemical relationships (Fig. 2).

Our age of 201.635 ± 0.029 Myr for the Kakoulima layered mafic intrusion in Guinea is the oldest age for CAMP magmatism. It is 150 ± 38 kyr older than the North Mountain basalt (NMB) and 71 ± 61 kyr older than the Amelal sill both of which were previously the oldest dated CAMP units and geochemical correlatives with the intermediate basalts in Morocco (Fig. 2). After the initial magmatism recorded in Guinea, the Messejana dyke (201.585 ± 0.034 Myr), Tarabuco sill (201.612 ± 0.046 Myr), Fouta Djallon sill (201.493 ± 0.051 Myr), Hodh sill (201.440 ± 0.03 Myr) and the Amazonas (low Ti) sills (201.525 ± 0.065 Myr) all intrude synchronously with the Palisades sill, York Haven, Rapidan, NMB and Amelal sills. Following these early events, the Amazonas high Ti sill (201.364 ± 0.023 Myr) and the Shelburne dyke (201.336 ± 0.084 Myr) are synchronous with the Freakness basalt and the Rossville intrusive. The Foum Zguid dyke (201.111 ± 0.071 Myr) occurs ~200 kyr afterward the initial magmatism and just before the Butner intrusive, which yields the youngest recorded U-Pb age for the CAMP. Magmatism from the whole province shows remarkable temporal and isotopic consistency over ~8,000 km (Fig. 2).

Hf isotopes. The Hf isotopic compositions of the dated zircon and baddeleyite grains were determined in order to better understand the source of the CAMP magmas and to ensure that the zircon analyses used in age calculations are all from the same source (that is, not xenocrystic). Individual Hf isotopic analyses from each sample were averaged to create a mean value for comparison with other CAMP magmas from this study. All of the magmas have εHf values ~0 ± 2 apart from the high Ti sample
from the Amazonas basin in Brazil, which has a more primitive εHf value of $\sim +7$. The broadly chondritic Hf isotopic composition of the low Ti CAMP samples (Fig. 2) suggests a similar magmatic origin and a relatively homogenous Hf isotopic signature over the entire length of the province. Other tracer isotope systems (Sr, Nd Pb and Os) have been previously used to investigate the source of the CAMP magmas, however these have been dominantly analysed by whole rock techniques and often show a large range in values suggesting variable amounts of crustal contamination or variable crustal input into the mantle source over the whole province (refs 30–35). The consistency of the zircon data suggests that (1) either the resolution of the technique is not at the required level to observe contamination, or (2) the contamination did not significantly alter the Hf isotopic composition of the samples. At present with the current resolution we cannot distinguish between the different possibilities.

The high εHf values from the high Ti samples from the Amazonas basin in Brazil are consistent with other tracer isotope systems suggesting that those magmas were derived from a depleted source distinct from that of the low Ti samples. Our new geochronology and Hf data is the first to conclusively show that the high Ti magmas occurred after the low Ti magmas.

**Discussion**

Our new data allow us to determine more precisely the relationship between the ETE and the CAMP. Importantly, our age of the Kakoulima intrusive indicates that CAMP magmatism was occurring $\sim 100$ kyr before the eruption of the basalt flows in Morocco and North America. Since these basaltic lava flows occur above the ETE carbon isotope excursion, the new ages presented here provide direct evidence for older CAMP activity synchronous with the extinction.

A compilation of proxy records across the ETE shows that the timing of early δ^{13}C excursions before the ETE in the Newark-Hartford, St Audrie’s bay, Stenlille and Kennecott Point records coincide with or just predate the newly discovered earliest CAMP magmatism (Fig. 3). Also, seismite occurrences before the ETE in the atmospheric and ocean chemistry; the onset of increases in atmospheric CO₂ suggested by leaf stomatal density data from Jamesonland, Greenland and also in Scania; increased stratification of the Panthalassic ocean recorded by the gammacerane index; reduction in bottom water oxidation recorded by homohopane increases; the onset of photic zone euxinia indicated by C_{18,22} aryl isoprenoids and isorenieratane levels and changes to the N cycle indicated by δ^{15}N variations, bivalve biodiversity decreases; and a dramatic decline in gymnosperm flora, all occur at the same time as the Kakoulima intrusive (Fig. 3).

![Figure 2](https://example.com/figure2.png)
The coincidence of these events does not indicate causality, however, the geochronology can be used to tentatively link the events before the ETE to early CAMP magmatism. An open question is whether the early intrusive magmatism is associated with undiscovered basalt flows, which could degas during eruption, or whether degassing from the intrusives themselves could cause the disturbances to the proxy records. Degassing of magmas at depth has previously been suggested as a cause of global disturbance before the eruption of LIP flood basalts. However, there is currently no known volatile rich magmatism (for example, kimberlites or carbonatites) at the same time as the Kakoulima intrusive which could suggest degassing of deep metamorphised rocks. We therefore, without further evidence, prefer not to speculate on early degassing of CAMP here.

After the onset of magmatism, marked by the Kakoulima intrusion, the majority of CAMP activity occurs coincident with, or just after the ETE1,3,5,18. The Messejane dyke in Spain, the Tarabuco mafic sill in Bolivia and importantly, mafic sills in the Amazon basin in Brazil occur synchronously with the 201.564 Myr age1 for the extinction (Fig. 2). The Amazon basin covers ~750,000 km² of NW Brazil and is broken into three sub-basins, the Amazonas (where the samples studied here are from the Solimoes and the Acre). These basins have a thickness of up to 4.5 km (ref. 40), and contain some of the country’s largest oil reserves, along with extensive Devonian shales and a Permo-Carboniferous evaporite sequence41,42. The intrusion of the CAMP sills into the Amazonas and Solimoes basins are known to have significantly altered the thermal history, causing oil generation and migration, as well as contact metamorphism of the organic and volatile rich sediments43. Polyaromatic hydrocarbons, which are likely created by burning and degassing of organics have been identified in the northern European basin1 where the identification of polycyclic aromatic hydrocarbons at the ETE horizon in the northern European basin11. Correlations are following ref. 2.

The coincidence of these events does not indicate causality, however, the geochronology can be used to tentatively link the events before the ETE to early CAMP magmatism. An open question is whether the early intrusive magmatism is associated with undiscovered basalt flows, which could degas during eruption, or whether degassing from the intrusives themselves could cause the disturbances to the proxy records. Degassing of magmas at depth has previously been suggested as a cause of global disturbance before the eruption of LIP flood basalts. However, there is currently no known volatile rich magmatism (for example, kimberlites or carbonatites) at the same time as the Kakoulima intrusive which could suggest degassing of deep metamorphised rocks. We therefore, without further evidence, prefer not to speculate on early degassing of CAMP here.

After the onset of magmatism, marked by the Kakoulima intrusion, the majority of CAMP activity occurs coincident with, or just after the ETE1,3,5,18. The Messejana dyke in Spain, the Tarabuco mafic sill in Bolivia and importantly, mafic sills in the Amazon basin in Brazil occur synchronously with the 201.564 Myr age1 for the extinction (Fig. 2). The Amazon basin covers ~750,000 km² of NW Brazil and is broken into three sub-basins, the Amazonas (where the samples studied here are from the Solimoes and the Acre). These basins have a thickness of up to 4.5 km (ref. 40), and contain some of the country’s largest oil reserves, along with extensive Devonian shales and a Permo-Carboniferous evaporite sequence41,42. The intrusion of the CAMP sills into the Amazonas and Solimoes basins are known to have significantly altered the thermal history, causing oil generation and migration, as well as contact metamorphism of the organic and volatile rich sediments43. Polyaromatic hydrocarbons, which are likely created by burning and degassing of organics have been identified in the northern European basin11 at the same time as the Amazonian gabbroic sill intrusions suggesting that the two are linked. Degassing of the Amazonian organic sediments would likely form pipe structures similar to those found in the Tunguska Basin in Russia where degassing of organic sediments was associated with the intrusion of sills from the Siberian Traps44. Pipes and associated metamorphic contact aureoles have not yet been identified in the Amazon basins, therefore it is difficult to estimate the volume and/or composition of gas released during degassing. However, the discovery that the sills intrude synchronously with the extinction quantitatively links CAMP magmatism with an important reservoir of volatiles, which would likely cause extensive atmospheric disturbance45.
crystallizing at a highly evolved, very late stage in the evolution of these mafic
ARTICLE NATURE COMMUNICATIONS | DOI: 10.1038/ncomms15596

mean age are observed, validating our chemical abrasion procedures. All zircons have undergone chemical abrasion treatment to remove the effects of Pb loss using chemical abrasion techniques; baddeleyite crystals were left untreated. Zircon crystals were annealed in a muffle furnace for 48 h at 900 °C and subsequently inspected under a microscope and transferred into three ml half-melting basalt for chemical abrasion. Concentrated HF + trace HNO3 was added to the beakers which were then placed into Parr bombs, and left in the oven at 180 °C for 15 h. After chemical abrasion, the remaining grain fragments (typically only fragments of grains were left after partial dissolution), flowed overnight in 6 N HCl at 80 °C and ultra-sonically cleaned in ∼ 3 N HNO3 at least four times, each time with new clean acid. Zircon crystals were then loaded into 200 µl microcapsules, spiked with ∼ 5 mg of EARTHTIME 202Pb, 203Pb, 204Pb, 234U, 235U, 238U tracer analytes (each in version 3.0, ref. 34) and dissolved in ∼ 70 µl concentrated HCl and trace HNO3 for 48 h at 210 °C in Parr bombs. Baddeleyite crystals were visually inspected using a binocular microscope and underwent the same ultrasonic cleaning procedure as zircon before being loaded into the microcapsules, spiked, and dissolved. After dissolution, the zircons were washed down and converted to chloride form and loaded onto columns filled with pre-cleaned anion exchange resin for U and Pb separation. The remainder from the U and Pb separation (the wash) was collected for further Hf purification. Once separated, the U and Pb fractions were recombined in pre-cleaned 7 ml Savillex beakers and dried down with trace 0.035 N HClO4 before loading on outsized single filament wires. The U and Pb samples were spiked with a 18O excess to 18O ratio of 0.99924, and for U, 233U/235U of 0.99506 was used along with a sample 238U/235U ratio of 0.123713U. Starting with the NMB age of 201.48 ± 0.02 Myr, which is a weighted mean of the NMB_03 age from this study, the age from ref. 5 and also the Westport drill hole age from ref. 1 (Supplementary Fig. 2).

Hf isotope methods. Zircon from mafic rocks typically contains high trace element contents so it is one of the only phases preferentially partitioning heavy rare earth elements. The high trace element contents results in high Yb/Hf ratios (Supplementary Data 2) and for this reason, measuring the Hf isotopic composition on the washes from U-Pb chemistry is not possible without purification. We used a simplified cation column chemistry procedure (similar to ref. 64) to purify the U-Pb washes so that they can be measured precisely on an MC-ICP-MS without isobaric interferences on 176Hf from Lu and Yb. Washes from the U-Pb column chemistry were collected in cleaned TPX beakers and dried down. They were then re-dissolved in an acid mix composed of 1 N HCl and 0.1 N HNO3 and added to cation exchange columns which had been pre-cleaned with multiple washes of 6 N HCl, 29 N HF and water. After passing the U-Pb washes through the column, they were dried down and re-dissolved in 2% HNO3 plus trace HF for MC-ICP-MS analysis.

Solution Hf isotope analyses were performed at the University of Geneva using a Thermo Neptune plus MC-ICP-MS equipped with nickel cones (Thermo X-series) under dry plasma conditions using Cetac ‘Aridus 2’ desolvation unit and a Telos nebulizer (~ 50 ml min⁻¹ uptake rate) following the procedure of ref. 63. The nine Faraday cups were configured to measure the following masses at low mass resolution (m/z ~ 450): 172 (L4), 173 (L3), 175 (L2), 176 (L1), 177 (C), 178 (H1), 179 (H2), 180 (H3), 181 (H4). The Plešovice and Temora zircon standards were run throughout the campaign at a Hf concentration of ~ 10 ppb to check for accuracy and reproducibility.

Many of the zircons measured in this study were small resulting in low concentrations of Hf, therefore Hf isotope measurements we employed following the short acquisition time measurements for the samples and sample-standard bracketing procedures outlined by ref. 63 with more concentrated Plešovice and Temora standards measured over a longer time to accurately determine the mass bias of the sample by standard bracketing. Sample measurements were made using a 50 × 1 s acquisition time and Plešovice measurements utilized a 60 × 3 s acquisition. Yb and Lu signals were monitored to check for isobaric interferences but the chosen column chemistry procedure was effective in reducing Yb and Lu to background levels. Correction for 176Hf in-growth due to 176Lu decay was corrected using a Lu/Hf of 0.001 which is similar to the Lu/Hf of the Temora zircon, changing this value by up to one order of magnitude results in an episodic unit change of ~0.09, which is much less than the external reproducibility of the Plešovice zircon (~1.6 episodic units), which was used as the uncertainty for all Hf data from the samples and standards is provided in Supplementary Data 3.

Data availability. The data shown and discussed in this paper is presented in full in the Supplementary Material.

Age of the north mountain basalt. The NMB has been dated by numerous studies, most of which produce similar ages of ~201 Myr. These studies include high precision U-Pb methods, lower precision U-Pb, Ar-Ar, and K-Ar. Of these dating techniques, only the high precision U-Pb studies are relevant here since the ~ percent level uncertainties for the other techniques preclude direct comparison with this study. This study and those of refs. 1.5 all used the same ET2535 spike during analysis, therefore the ages should be directly comparable. The age of 201.48 ± 0.02 Myr (updated to the current spike isotopic composition by ref. 22) was from a maﬁc pegmatite in Mount Pleasant quarry in the East Ferry Member (EFM) of the NMB, which is the lowest unit of the basalt. The NMB_03 sample dated here at 201.52 ± 0.028 Ma is from the same pegmatite and both of our ages overlap within uncertainty. Reference 1 dated two samples from the EFM, one from the Mount Pleasant quarry, another from the Westport drill hole on the Brier Island. The Mount Pleasant quarry, which has an age of 201.566 ± 0.033 Myr, overlapping with the NMB age reported here, but not that of ref. 5. The NMB_03 sample dated here at 201.53 ± 0.02 Ma is from the same pegmatite and both of our ages overlap within uncertainty. Reference 1 dated two samples from the EFM, one from the Mount Pleasant quarry, another from the Westport drill hole on the Brier Island.

Acknowledgements

This study was supported by the Swiss National Science Foundation (project number 162341). Partial funding was also provided by the following collaborative research projects: (i) PICS, CNRS (France)-CNRST (Morocco) to H.B. and N.Y. and (ii) CNRi (Italy)-CNRST (Morocco) to A.M. and N.Y. and we also acknowledge financial support from Padova University, CPDA132295/13, and from PRIN 20158A9CBM to A.M.

Author contributions

U.S. and A.M. devised the project, J.H.F.L.D. collected the data, all authors contributed to the ideas and writing of the manuscript.
