Relation Regularized Scene Graph Generation

Yuyu Guo, Lianli Gao, Jingkuan Song, Peng Wang, Nicu Sebe, Heng Tao Shen Fellow, ACM, and Xuelong Li Fellow, IEEE

Abstract—Scene graph generation (SGG) is built on top of detected objects to predict object pairwise visual relations for describing the image content abstraction. Existing works have revealed that if the links between objects are given as prior knowledge, the performance of SGG is significantly improved. Inspired by this observation, in this paper, we propose a Relation Regularized Network (R2-Net), which can predict whether there is a relationship between two objects and encode this relation into object feature refinement and better SGG. Specifically, we first construct an affinity matrix among detected objects to represent the probability of a relationship between two objects. Graph Convolution Networks (GCNs) over this relation affinity matrix are then used as object encoders, producing relation-regularized representations of objects. With these relation-regularized features, our R2-Net can effectively refine object labels and generate scene graphs. Extensive experiments are conducted on the Visual Genome dataset for three SGG tasks (i.e., PREDCLS, SGCLS, and SGDET), demonstrating the effectiveness of our proposed method. Ablation studies also verify the key roles of our proposed components in performance improvement.

Index Terms—Scene graph generation, visual relationship, graph convolution networks.

I. INTRODUCTION

IN PRACTICE providing only object labels and detecting object bounding boxes [1]–[5] may not produce satisfactory semantic information for downstream tasks, such as visual content retrieval [6]–[9], visual question answering [10], [11] and visual captioning [12], [13]. For instance, in Fig. 1, generated object labels and bounding boxes (e.g., dog, woman, frisbee, and hair) cannot provide answers to the following question: What are the two dogs and the woman doing? As a result, scene graph generation has been proposed and studied by Krishna et al. [14], who also collected a dataset consisting of images with objects and object relations to evaluate the quality of the generated scene graph. In the example in Fig. 1, the bottom part represents the scene graph, precisely and briefly describing the semantic content of the top image. With such a scene graph, we can provide an answer to the aforementioned question. As shown in Fig. 1, a scene graph consists of nodes (objects) and edges (relationships between objects). Given an image, scene graph generation is built on top of detected objects to predict object pairwise visual relations for describing the image content abstraction [15]–[17]. It is challenging to effectively and accurately generate a scene graph and this has been recently the subject of intensified research [15]–[19]. Some studies have focused on exploiting linguistic priors [15], visual embedding [18], feature interactions [20], external information (e.g., region captions) [21] or spatial information [19] to boost the performance. Some other studies have tried to extract certain contextual information from objects to enhance the performance [16], [17], [22] by iterative message passing, neural motifs, or graphs to avoid detecting and recognizing individual objects in isolation.

From previous works, we can see that the contextual information is important to scene graph generation. To truly produce accurate scene graphs, it is crucial to devise a model that fully and automatically exploits global contextual information and relational contextual information. The global contextual information encodes the visual information from all objects and backgrounds/environments. The relational contextual information encodes the graph information among objects. Moreover, the previous experimental results of the two scene graph generation tasks (i.e., PREDCLS and SGCLS) [16], [17], [19] have proved that the quality of the detected object labels significantly influences the performance of the scene graph generation. In other words, improving the quality of object label detection could directly lead to better scene graphs.

Therefore, in this paper, we address the problem of scene
graph generation, where we aim to take advantage of the global context and relational information to produce a relation regularized scene graph from an image. Our contributions are three folds: 1) We propose a novel relation regularized network, namely R2-Net, which can predict whether there is a relationship between two objects and use this relation as a regularizer to learn relation-embedded features. Therefore, the R2-Net effectively and progressively encode region features with the global context and relational information to refine object label prediction and scene graph generation; 2) We propose a stacked LSTM-GCN encoder to extract the comprehensive features of objects. Specifically, we stack GCNs on top of Bi-LSTMs as an object feature encoder to combine the relation-embedded features and the global features. 3) We verify the effectiveness of our method across three tasks (i.e., PREDCLS, SGCLS, and SGDET) on the Visual Genome dataset. Our ablation study also demonstrates the key roles of our proposed components in performance improvement.

II. RELATED WORK

In this section, we describe three categories of related works, including object detection, scene graph generation and graph convolutional networks.

Object Detection. Object detection is one of the most fundamental areas in the field of computer vision. Owing to the evolution of Convolutional Neural Networks (CNNs) [23], many effective CNN-based methods [4], [5], [24]–[27] have been proposed to deal with this task. At first, Girshick et al. [24] directly extracted the deep features of warped region proposals with a deep CNN and classified these deep region features with SVMs [28]. However, performing a whole CNN forward pass for each proposal is time-consuming. Fast R-CNN [25] extracted the feature map from an entire image and mapped region proposals to regions of interest (RoIs) in the feature map. Then, the RoIPooling layer resized the RoI feature maps to the same size for classification and regression. By sharing the same CNN for region proposals, Fast R-CNN saved a lot of computing time. In order to achieve real-time detection, Faster R-CNN [5] replaced the time-consuming Selective Search method with a region proposal network to search for the class-agnostic foreground objects. Previous methods with the RoI pooling layer may cause coarse quantization on feature maps. To alleviate this problem, He et al. [27] proposed the RoIAlign layer, which preserves precise spatial mappings. Different from the above works, this paper focuses on a more complex problem: scene graph generation. To solve this problem, we need not only to detect objects in the image but also to extract contextual information to predict the relationships among objects.

Scene Graph Generation. Object detection cannot adequately represent rich semantic information in images, and therefore more and more works [14], [15], [17]–[19], [21], [29], [30] pay attention to scene graph generation (or visual relationship detection) for exploring rich semantic information in images. Since the relationships between objects largely depend on human prior knowledge, Lu et al. [15] integrated a visual module and a language module for adequately employing human prior knowledge. Inspired by translating embeddings [31] for modeling multi-relational data, Zhang et al. [18] proposed the Visual Translation Embedding (VTE) network. In VTE, entities are embedded in a semantic space, and relationships are modeled as a vector translation: subject-object ≈ relation. Due to the effectiveness of end-to-end convolutional neural networks, Newell et al. [32] proposed end-to-end convolutional networks that mapped pixels to graphs directly with associative embedding.

All the above works use the local detectors and independently predict relationships between entities. As mentioned in [17], ignoring the surrounding context may lead to ambiguity of model prediction. Therefore, for capturing the surrounding context in images, the authors inferred scene graphs by iteratively refining model predictions with recurrent neural networks. In addition, Zeller et al. [16] explored regularly appearing substructures called motifs in scene graphs. Inspired by this analysis, the authors proposed a strong baseline. The baseline determines the relationship between two objects through two steps: 1. Determining the labels of objects by Faster R-CNN [5]; 2. Finding the most frequent relationship between the two objects’ labels (ignoring the visual information) in the training set. Then the authors combined the baseline and LSTMs for extracting global context and outperformed the state-of-the-art methods. By analyzing the above works, we find that if the links between objects are given as prior knowledge, the performance of scene graph generation would be significantly improved. Inspired by this observation, we propose a Relation Regularized Network (R2-Net), which can predict whether there is a relationship between two objects, and encode this relation with GCNs to refine features and generate robust scene graphs.

Graph Convolutional Networks (GCNs). In order to extract features on graph-structured data, Kipf et al. [33] proposed Graph Convolutional Networks (GCNs) for semi-supervised node classification based on spectral graph convolutions. Given a graph, GCNs refine node features based on the adjacency matrix and encode graph structures by passing information between adjacent nodes. Due to the effectiveness of GCNs, several works [34]–[36] introduced GCNs into different fields. For instance, Marcheggiani et al. [35] used GCNs for semantic role labeling (SRL). They stacked GCNs on LSTMs to capture different ranges of information. Schlichtkrull et al. [34] proposed Relational Graph Convolutional Networks (R-GCNs) for link prediction and entity classification on knowledge graphs. In addition to the graph structure data, GCNs were also applied to computer vision tasks. In order to predict human-object interactions (HOIs) in images, Qi et al. [36] expressed HOI structures as graphs. The information between instances can be effectively captured by GCNs. Different from these works, we focus on scene graph generation. Since the task of scene graph generation does not give the affinity matrix in the test phase, we first construct the affinity matrix from the image. Next, GCNs are used to encode the instance features with the affinity graph. In this way, our model can generate robust scene graphs with the graph level features.
### III. Relation Regularized Model

In this paper, we propose a relation regularized model for the scene graph generation. The overview of our proposed model is depicted in Fig. 2. The framework consists of three components: 1) Object detection (i.e., bounding box detection and prior object label detection); 2) Relation regularized label refiner; and 3) Relation regularized relationship generation. In the following subsections, we first introduce the definition of our problem and then describe the details of the model from inputs to outputs (Object Detector, Object Label Refiner, Object Relationship Generator, and Loss Functions). Since this section contains many symbols, we show the dimensions and descriptions of the main symbols we use in Tab. II.

#### A. Problem Definition

We define the image scene graph generation problem as follows: Given an image $I$, we want to generate a scene graph $G$ to describe its content abstraction. Following previous works [6], [16], we determine to progressively decompose the scene graph generation into a series of continued actions: bounding boxes detection $B$, bounding box label detection $L$ and label relation detection $R$. Therefore, $G$ is defined as $G = \{B, L, R\}$. The probability of $G$ is decomposed by a multiplication rule:

$$P(G|I) = P(B|I)P(L|B, I)P(R|L, B, I).$$

#### B. Object Detector

The object detector is utilized to detect instances in images. The inputs of the object detector are images, and the outputs are bounding boxes, categories, and features of instances. Faster R-CNN [5] has achieved great success in image object detection, and it has been widely adopted to support image scene graph generation [16]–[18], [22]. In this paper, we adopt Faster R-CNN to generate a set of bounding boxes.
However, directly using deep LSTMs may exist the problems of training difficulty and slow convergence. In order to alleviate such issues, the highway LSTM [40] was designed by connecting memory units of adjacent LSTM layers, and this structure [38], [40] has been used predominantly to achieve state-of-the-art results for semantic labeling, language modeling, etc. Therefore, we use stacked Bi-LSTMs with highway connections to encode object features $\mathbf{F}$ to alleviate the problems caused by deep LSTMs:

\[
i_{k,t} = \sigma(W_i^f[k_{t,k} + \delta_k, x_{k,t}] + b_i^k),
\]
\[
o_{k,t} = \sigma(W_o^f[k_{t,k} + \delta_k, x_{k,t}] + b_o^k),
\]
\[
f_{k,t} = \sigma(W_f^f[k_{t,k} + \delta_k, x_{k,t}] + b_f^k),
\]
\[
r_{k,t} = \sigma(W_r^f[k_{t,k} + \delta_k, x_{k,t}] + b_r^k),
\]
\[
g_{k,t} = \tanh(W_g^f[k_{t,k} + \delta_k, x_{k,t}] + b_g^k),
\]
\[
c_{k,t} = f_{k,t} \circ c_{k,t} + i_{k,t} \circ g_{k,t},
\]
\[
h_{k,t} = o_{k,t} \circ \tanh(c_{k,t}),
\]
\[
h_{k,t} = r_{k,t} \circ h_{k,t} + (1 - r_{k,t}) \circ W_h^r x_{k,t},
\]

where $x_{k,t}$ is the input to the $k$-th LSTM layer at timestep $t$, $W_i^f$ and $b_i^k$ are parameters, and $\delta_k$ indicates the direction of $k$-th LSTM layer. The operator $\circ$ represents the Hadamard product (also known as the element-wise product). The function $\sigma$ represents the sigmoid function. Following He et al. [38], we set the inputs $x_{k,t}$ and $\delta_k$ of each LSTM layer as follows:

\[
x_{k,t} = \begin{cases} f_t & k = 1 \\ h_{k-1,t} & k > 1 \end{cases},
\]

(3)

\[
\delta_k = \begin{cases} 1 & k \mod 2 = 0 \\ -1 & k \mod 2 = 1 \end{cases},
\]

(4)

where $f_t$ is the $t$-th bounding box feature of $\mathbf{F}$ extracted from the Faster R-CNN as mentioned in Sec. III-B. The outputs of the highway LSTMs are denoted as $\mathbf{H} = \{h_1, h_2, ..., h_N\}$. The data stream of Bi-LSTMs with highway connection is shown as 3.

Graph Convolutional Networks (GCNs) [33]–[35] produce an optimized node-level output, which encodes both original node features and the associations between data nodes. By using GCNs, our model can integrate the information of related objects to boost the performance of the label prediction.

With Faster R-CNN and stacked Bi-LSTMs, we can obtain a set of global features $\mathbf{H} = \{h_1, h_2, ..., h_N\}$ corresponding to previously detected $N$ objects. By considering each object feature as a node, we take the global features $\mathbf{H}$ to estimate an adjacency matrix $\mathbf{A}^e = \{a_{i,j}^e, ..., a_{N,N}^e\}$, where $a_{i,j}^e \in \mathbb{R}^1$ represents whether a relationship exists from object $i$ to object $j$.

In the process of scene graph generation, an object label may act as a subject or an object in a scene graph. Thus we firstly adopt two fully connected layers to map $h_i$ into a subject space domain and an object space domain, respectively.

\[
h_i^s = FC^s_h(h_i),
\]
\[
h_i^f = FC^f_h(h_i).
\]

(5)

The output dimensions of the two fully connected layers are $D_f$. Next, we apply a simple and effective scoring function, DistMult [41], to compute affinity matrix scores:

\[
a_{i,j}^e = \sigma((h_i^s \circ u_{i,j})^T W_o^e(h_o^f \circ u_{i,j}) + b_{i,j}^e),
\]

(6)

C. Stage I: Object Label Refiner

To efficiently and effectively evaluate a scene graph generation model, previous works [16]–[18], [22] have designed two experiments: SGCLS and PREDCLS (see details in Sec. IV-C). All existing experimental results [16]–[18], [22] have shown that the scores (recall@20, 50, 100) of PREDCLS are significantly higher than those of SGCLS by approximately 30%. Both SGCLS and PREDCLS take ground truth boxes as inputs, but PREDCLS adopts the ground truth labels, while SGCLS takes the predicted object label. These results [16] prove the importance of accurate object labels for scene graph generation.

In other words, how to improve the prediction accuracy of object labels is the key to solving the scene graph generation problem.

Therefore, in the second step, we aim to improve scene graph generation by refining the object labels generated by the Faster R-CNN network. The inputs of the Object Label Refiner are instance features, bounding boxes, and categories, and the outputs are refined object categories. When generating object labels, the Faster R-CNN neither considers the global context [16] nor object relations. Thus, we propose a relation regularized module for label refinement with a stack of Bi-LSTM [37]–[39] to capture the global context and a relation based graph convolution layer [33]–[35] to make full use of object relationships.

Relation Regularized Label Encoder. In our work, we use deep bidirectional LSTMs to explore the global context.
where $W^a \in \mathbb{R}^{D_I \times D_I}$ is a diagonal parameter matrix that the model needs to learn, $b_{a,i,j}^r \in \mathbb{R}^1$ is a bias specific to the subject $i$ and object $j$ labels. Following [16], we initialize the bias with the frequency of the training set. $\sigma$ is an activation function mapping the score ranging from 0 to 1. Besides, giving two objects it is difficult to determine the information flow direction from the object to the subject or vice versa. Therefore, the adjacency matrix is adjusted to form a symmetric matrix $A^s$ to solve this issue:

$$a^s_{i,j} = \begin{cases} a^e_{i,j} & \text{if } a^e_{i,j} \geq a^o_{j,i} \\ a^o_{i,j} & \text{if } a^e_{i,j} < a^o_{j,i} \\ 1 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}. \quad (7)$$

With the generated symmetric matrix $A^s$, we integrate Bi-LSTMs with GCNs to obtain relational features $O = \{o_1, \ldots, o_N\}$:

$$O = \text{ReLU}(D^oA^sHW^G), \quad (8)$$

where $W^G$ is a parameter matrix. $D^o = \{d^o_{1,1}, \ldots, d^o_{N,N}\}$ is a diagonal matrix:

$$d^o_{i,j} = \begin{cases} 1 & \text{if } i = j \\ \frac{\sum_{k=1}^n a^e_{i,k}}{\sum_{k=1}^n a^e_{i,k}} & \text{if } i \neq j \end{cases}. \quad (9)$$

Next, we concatenate the global context $h_i$ and the relational feature $o_i$ to form the final output $o'_i$:

$$o'_i = [o_i, h_i]. \quad (10)$$

For simplicity, we define the whole Relation Regularized encoding process as:

$$\{A^s, O\} = \text{R2-Encoder}(F|W^o), \quad (11)$$

where $W^o$ is the parameter in the Relation Regularized module.

**Label Decoder.** Finally, we use an LSTM layer with Highway gate to decode $O'$. After refining the previous generated initial object labels $L$, we obtain the refined object label $L^d$:

$$q^d_i = \text{LSTM}([l^d_{i-1}, q^d_{i-1}, o'_i]), \quad (12)$$

$$l^d_i = \text{argmax}(Wq^d_i + h_i), \quad (13)$$

where $l_i$ is the prior label distribution from Faster R-CNN as mentioned in Sec. III-B. $q^d_i$ is the hidden state of LSTM. $l^d_i$ is $i$-th the refined object labels $L^d$. In addition, we set $\langle BOS \rangle$ as the start signal for the decoding process.

### D. Stage II: Object Relationship Generator

The Object Relationship Generator predicts the relationship predicate $R$ between instances with instance features $O'$ from Eq. 11 and refined labels $L$ from Eq. 12.

**Relation Regularized Relationship Encoder.** With Faster R-CNN and our proposed relation regularized label generation module, we can transfer an image into a set of optimized instance features $O'$ and refined labels $L^d$. Next, we apply our proposed relation regularized encoder to facilitate the relationship prediction process:

$$\{A^r, Z\} = \text{R2-Encoder}([O', W^dL^d]W^z). \quad (14)$$

where $W^d$ is the embedding parameter and is initialized by Glove [42], and $Z = \{z_1, \ldots, z_N\}$ is the output feature of R2-Encoder in the Relationship Generator phase. $Z$ is similar to $O'$ in Eq. 11 and contains the global and relational features in the Relationship Generator.

**Relationship Decoder.** Next, we obtain the object relationship by firstly mapping $z_i$ into two feature space domains: subject domain and object domain, $z^s_i$ and $z^o_i$ respectively:

$$z^s_i = FC^s_h(z_i), \quad z^o_i = FC^o_h(z_i). \quad (15)$$

We then employ the DisMult score function to compute the object relations:

$$r_{m,i,j}^r = (z^s_i \circ u_{i,j})^T W^r_m(z^o_j \circ u_{i,j}) + b^r_{m,i,j}, \quad (16)$$

where $r_{m,i,j}^r$ is the probability that the object $i$ and object $j$ belong to the relationship $m$. $W^r_m$ is a diagonal parameter matrix that needs to be learned. $b^r_{m,i,j}$ is the frequency bias mentioned in [16]. Finally, we use a softmax function to obtain the final relation score ranging from 0 to 1:

$$r_{m,i,j} = \frac{e^{r_{m,i,j}}}{\sum_{m=1}^{n} e^{r_{m,i,j}}}, \quad (17)$$

where $D_r$ is the number of relationship categories in the dataset. Now we can get the final relationships $R = \{r_{1,1}, \ldots, r_{D_r,N,N}\}$.

### E. Loss Functions

In this section, we first describe two objective functions. The first one is the label prediction loss $L_1$ for refining the object labels, while the second loss is relation regularized loss (R2-loss $L_2$) for learning the first adjacency matrix:

$$L_1 = \text{Cross_Entropy}(L^d, L^g), \quad L_2 = \text{Cross_Entropy}(A^s, A^g), \quad (18)$$

where $L^d$ is the output from Eq. 12, and $L^g$ is the ground truth object labels. $A^s$ is obtained by Eq. 6, $A^g$ is the ground truth adjacency matrix, which is used to indicate whether there is a relationship between two entities, i.e., 0 or 1.

To learn the parameters for generating relations between objects, we describe two object functions to control our model:

$$L_3 = \text{Cross_Entropy}(A^r, A^g), \quad L_4 = \text{Cross_Entropy}(R, R^g), \quad (19)$$

where $L_3$ is another relation regularized loss at the relationship generation phase, and $L_4$ is the object relationship loss (R2-loss). The proposed final objective function of our proposed a relation regularized model is defined as the sum of $L_1, L_2, L_3$ and $L_4$.

### IV. EXPERIMENTS

In this section, we evaluate our model on the cleaned Visual Genome dataset [14]. Some experiments are conducted to test the role of the major components and to compare our model with the previous methods.
A. Experimental Setting: Dataset

Krishna et al. [14] collected and officially released a knowledge base to connect structured images concept to languages, namely Visual Genome dataset. They have collected more than 100k images. On average, each image contains 38 objects and 22 pairs of object relations. This is an ideal candidate dataset for evaluating scene graph generation models. However, some annotations are ambiguous and may lead to predicting errors. Many cleaning approaches have been proposed, such as [17], [21], [29]. In particular, Xu et al. [17] proposed a cleaning strategy to remove ambiguous annotations. This strategy has been widely adopted by previous scene graph generation methods, such as [15]–[17], [22], [32]. After cleaning, each image, on average, contains approximately 12 objects and 6 pairs of relationships. In total, the cleaned Visual Genome dataset contains 150 object categories and 50 object relation classes. Moreover, we follow Xu et al. [17] to divide the cleaned dataset into two subsets: 70% training and 30% testing. Next, we follow [15]–[17], [22], [32] to select 5k images from the training dataset as the validation set.

B. Experimental Setting: Implementation Details

For object detection step, we follow the previous works [16], [17] to adopt the Faster R-CNN model as the object detector to generate a set of bounding boxes and their corresponding features and labels. More specifically, previous works [16], [17], [22], [32], [43] adopt the VGG16 network as the backbone of pre-trained Faster R-CNN. For a fair comparison, we also adopt the VGG16 based Faster R-CNN network, which is pre-trained on the Visual Genome object dataset by Zellers et al. [16]. For the VGG16 based Faster R-CNN network, we obtain the region features from the output feature map of the second fully connected layer.

By using ResNet101 to extract deeper features, previous work [5] has proven that ResNet101-based Faster R-CNN can perform better than VGG16-based Faster R-CNN on the object detection task. Better region features and more accurate object labels may be conducive to object relation generation. Therefore, we first take the ResNet101 [3] as the backbone of the Faster R-CNN and then train the ResNet101-based Faster R-CNN on the training set of the cleaned Visual Genome dataset. More specifically, the detector is trained on a Titan Xps (12 GB) with the SGD optimizer. The learning rate and batch size are set to $2 \times 10^{-2}$ and 24, respectively. When training our model on the scene graph detection (SGDET), we fine-tune our model following the strategy mentioned in [16] for fairness. We sample 256 Region of Interests (RoIs) in each image. After the label decoder in the object label refiner, we use the per-category Non-Maximum Suppression (NMS) to filter redundant objects.

Our codes are implemented in python. We use Pytorch to build our model. All experiments are conducted on a Ubuntu server with 2 Titan Xps (12 GB), 4 Intel(R) Xeon(R) E5-2650 CPUs and 256 GB RAM.

C. Experimental Setting: Evaluation Strategy

Following previous works [17], [22], [32], we evaluate our model with three experimental setups: 1) The PREDCLS (predicate classification) allows models to take the ground truth bounding boxes and the ground truth object labels as inputs. 2) The SGCLS (scene graph classification) allows models to take the ground truth bounding boxes as inputs. And 3) The SGDET (scene graph detection), which requires a model to take an image as inputs and then predict object bounding boxes, object labels, and object relations. Tab. II shows what information a task needs to predict. Since the PREDCLS task allows models to take the ground truth bounding boxes and the ground truth object labels as inputs, it only requires models to predict relational predicates. However, the SGCLS task requires models to predict relationship predicates.
TABLE IV
THE ROLE OF BI-LSTMS AND GCNS IN R2-NET. THE RESULTS ARE OBTAINED ON THE VALIDATION DATASET.

| R2 Variants | SGCLS | PREDCLS |
|-------------|-------|---------|
| w/o Bi-LSTM1 | R@20 | 39.1 | 35.9 | 35.9 |
| w/o Bi-LSTM2 | R@50 | 41.9 | 39.6 | 39.6 |

| sitting on | 78.9 | flying in | 0.0 |

and object labels, and the SGDET task requires models to predict relationship predicates, object labels and object bounding boxes. In other words, SGDET is the most difficult one, while PREDCLS is the easiest one. Moreover, in order to provide a more consistent comparison, we also report the corresponding results of the three setups without scene graph constraints.

The object relations in the Visual Genome dataset are sparse, thus using the mean average precision (mAP) as the evaluation metric would falsely punish positive predictions on unannotated relations. As a result, we follow previous works [15]–[17], [32] to evaluate our model with recall@K (i.e., R@K). More specifically, R@K describes the proportion of ground truth triplets (i.e., obj1-relation-obj2) in the top K predicted triplets. The K is set as 20, 50 and 100. Besides, for the SGDET task, if the object has at least 0.5 IoU overlapping with the ground truth box, it is considered as correctly detected.

D. Results and Analysis: Speed of R2-Net

Regarding the speed of our model, in the training phase, each epoch (about 57k images) takes 40 minutes for the SGCLS task and 210 minutes for SGDET. In the testing phase, our model takes about 0.12 seconds to parse a single image for SGCLS and PREDCLS, and 0.33 seconds for SGDET. These results are obtained under the experimental environment mentioned in Sec. IV-B.

E. Results and Analysis: Ablation Study

In order to deeply analyze the proposed approach and demonstrate its effectiveness, we present an extensive ablation study on the Visual Genome dataset by considering different variants of the proposed R2-Net to evaluate its major components. In this section, the experimental results are obtained from the validation dataset and we choose ResNet101 based Faster R-CNN network as our object detector.

Effect of Object Label Refiner We consider three R2-Net variants: 1) w/o refiner where R2-Net performs the scene graph generation with only two components. The object detector is followed by an object relation generator; 2) w/o prior labels where the object label refiner without the prior labels mentioned in Eq. 12; 3) All where R2-Net performs the task with all three components: object detector, object label refiner and object relation generator. We carry out the experiments, as shown in Tab. III. It can be observed that all significantly performs better than w/o refiner on the SGCLS task with an increase of 6.6% on R@20, 3.5% on R@50 and 2.2% on R@100, while slightly outperforms the label detection by 1.2% in terms of accuracy. The experimental results prove that our proposed label refiner is able to extract more representative features for both object label classification and scene graph generation. Compared with w/o prior labels, using prior labels can improve 1.2% on SGCLS (R@20) and 0.8% on object accuracy. Therefore, we use prior labels in the object label refiner to make the model easier to learn.

Effect of Relation Regularized Encoder Our R2-Net consists of two relation regularized encoders. The first one is proposed for supporting the object label refiner, while the second one is designed for facilitating the object relationship generation. Both encoders consist of two components: 1) highway based Bi-LSTMs for capturing the global context and 2) object relation based graph convolutional layers for learning object relations. In order to deeply evaluate the effect of Bi-LSTMs and relation regularized GCNs of the two encoders, we design a set of R2-Net variants by removing the Bi-LSTMs of the first encoder (w/o Bi-LSTM1), removing the Bi-LSTMs of the second encoder (w/o Bi-LSTM2), removing the GCNs of the first encoder (w/o GCN1), removing the GCNs of the second encoder (w/o GCN2), removing all GCNs of the two encoders (w/o GCNs), removing all Bi-LSTMs of the two encoders (w/o Bi-LSTMs), and the full R2-Net (All).

The experimental results are shown in Tab. IV and we have the following observations: 1) compared with All, w/o Bi-LSTM1 decreases the R2-Net performance more by 0.8% R@20, 0.7% R@50 and 0.6% R@100. This demonstrates the effectiveness of the proposed Bi-LSTM1 for encoding global context; 2) removing either GCNs (GCN1 or GCN2) could lead to a drop in both tasks, scene graph generation and label

|                   | R2-Net (w/o GCN1) | 32.9       | 38.6       | 45.4        | 48.8       | 81.0       | 88.4        | -            |              |              |
|                   | R2-Net       | 30.4       | 36.0       | 46.6        | 49.9       | 81.3       | 88.2        | -            |              |              |
|                   | SL+RL        | CMAI [47]  | 31.6       | 36.8        | 48.6       | 52.0        | 58.3        | 83.2         | 90.1         |              |

The experimental results demonstrate that on the SGCLS task, the ResNet101-based model is obviously better than the corresponding VGG16-based model. Interestingly on the PREDCLS task, the VGG16-based models achieve higher scores than the corresponding ResNet101-based ones. In addition, with the same evaluation metrics and the same backbones, the performance score obtained on the PREDCLS task is around twice higher than the score reached from the SGCLS. From the experimental results, we can conclude that scene graph generation is largely depending on the accuracy of the object label prediction, while the label prediction accuracy is mostly relying on the region features. The more representative the region feature is the more accurate the object label prediction is. Moreover, from the experimental results, we can see that higher level features have only a slight effect on object label relation generation. More importantly, our R2-models significantly outperform the previous best method Motifnet on both two tasks, reaching the new state-of-the-art.

**Which of the predicates perform better/worse?** We investigate the performance of each predicate on the PREDCLS task (R@100) without graph constraints. In Tab. VI, the top ten predicates with the highest score are shown on the left side and the bottom ten predicates with the lowest score are shown on the right side. By analyzing the dataset, we find that the samples of the top ten categories account for 78.9% of the total dataset, while the samples of the bottom ten categories account for only 1.3% of the total dataset. Therefore, the imbalance of the dataset is the main reason for the huge difference in predicate scores.
Fig. 4. Some qualitative examples produced by our R2-Net (w/o GCN1) on the SGDET. Predicted true positive boxes are marked with green (IOU > 0.5). Orange boxes are ground truth boxes but not detected. For simplicity, we demonstrate the top 20 object relations or edges at the R@20 setting. Predicted true positives relations are marked with green arrows, false negative relations are marked with orange arrows, and false positive relations are marked with blue arrows.

F. Results and Analysis: Comparison with State-of-the-art Methods

In this section, we compare our proposed R2-Net with several state-of-the-art methods, including Visual Relation Detection (VRD) [15], Iterative Message Passing (IMP) [17], Tensorize Factorize Regularize (TFR) [45], Associative Embedding (AE) [32], Graph R-CNN [22], FREQ+OVERLAP [16], and Motifnet [16]. We cannot compare our method with Factorisable Net [19], DR-Net [29], and MSDN [21], because the approaches for data cleaning and splitting are different. Besides, Factorisable Net [19] has proven that the more bounding boxes generated, the better performances of scene graph generation are. However, the more bounding boxes are chosen, the more complex the computation is. Motivated by this, for the task of SGDET we choose the top 64 regions detected by the Faster R-CNN, following previous works [16], [17], [45]. To fully evaluate our method, we apply two evaluation strategies: with and without graph constraints. The experimental results are shown in Tab. VII (with graph constraints) and Tab. VIII (without graph constraints). From them, we can see that with two experimental settings, our R2-Net performs the best on all three tasks with the supervised learning strategy, which confirms the effectiveness of our proposed method. Compared with the methods using reinforcement learning, our R2-Net (w/o GCN1) still achieves better results on the SGDET task. Because it is not practical to provide the ground truths of object bounding boxes or categories for models in real life, the SGDET task has more practical value than SGCLS or PREDCLS. Therefore, our method is superior to VCTREE and CMAT in some aspects.

More specifically, as shown in Tab. VII, R2-Net without graph convolutional layers (GCN1) of the first relation regularized encoder achieves the highest scores for the SGDET task, reaching 23.1% on R@20, 29.4% on R@50, and 33.0% on R@100, which is significantly higher than the R2-Net. However, for the task of SGCLS, the performance result is
opposite. Also, with the same metric and model, the score of the task SGCLS is around 10% higher than the score of the SGDET task. These experimental results clearly demonstrate the effectiveness of the accurate bounding boxes and confirm that bounding boxes with noise could lead to a failure of object relation matrix construction, thus further decreasing the role of GCN1. Moreover, for the task of PREDCLS, the performance of R2-Net (w/o GCN1) and R2-Net is almost the same. As mentioned in the Ablation Study (i.e., Sec. IV-E), the object relation prediction is largely depending on the accuracy of the object labels instead of the object region features. Therefore, with ground truth object labels, using GCN1 to improve the region features could not considerably improve the performance of the object relation prediction process.

G. Results and Analysis: Qualitative Results

We show some qualitative examples in Fig. 4 obtained by our R2-Net (w/o GCN1) on the SGDET. From the first column, we can see that our model not only predicts relationships in the ground truth but also predicts relationships not in the ground truth, such as (pot-1, has, handle-1), (boat-2, has, dog-1), (tie1, on, shirt-1), and (hair, on, head-1). From the second column, we can see that undetected bounding boxes are a major reason for leading to relation generation failures. For instance, railing GT1 and logo GT1 in the first row, tire GT1 in the second row, paw GT1 in the third row and leg GT1 in the bottom, are not detected. Therefore, the relations correlated with them are not detected.

We also show some affinity matrices (Aeq and Ar mentioned in Eq. 11 and Eq. 13) in Fig. 5. From examples on the left side, both Aeq and Ar can properly predict whether there is a relationship between instances. However, in the examples on the right side, the visual link prediction of Ar is better than Aeq. For instance, Ar can provide correct links of the following object pairs: (plane-1, tail-1), (man-1, wheel-2), (wheel-1, skateboard-1), and (food-2, plate-1). In the right bottom example, food-2 (i.e., soup and bread) contains food-1 (i.e., bread), but the relationship category between food-2 and food-1 is not contained in the Visual Genome dataset. Therefore, in the affinity matrix Ar, the value of the object pair (food-1, food-2) is small. The reason why the prediction of Ar is better than Aeq includes two aspects. First, after the Object Label Refiner, the prediction of the object label is improved. Second, the residual connection allows the Object Relationship Generator to receive more robust features.

V. Conclusion

In this paper, we propose a novel model for parsing visual scene graphs, namely Relation Regularized Network (R2-Net). It predicts whether there is a relationship between two objects and generates an affinity matrix. GCNs over the affinity matrix aggregate the related object features to the target object features. In this way, the model can integrate the information of related objects to boost the performance of the label prediction. BiLSTMs are used to extract the global contexts of objects. By encoding object features with global context and relational information, the relation regularized module can effectively refine the prior labels from Faster R-CNN and predict the relationships between objects. Compared with other methods, our model produces more accurate object labels and
more robust relationship features, so our model outperforms the state-of-the-art methods on the scene graph generation task. Extensive experiments on the Visual Genome dataset demonstrate the effectiveness of our method.

Peng Wang received the Ph.D. degree from the University of Queensland in 2017. He was a Research Fellow with the Australia Institute of Machine Learning (AIML), The University of Adelaide. He is currently a Lecturer with the School of Computing and Information Technology, University of Wollongong (UOW), Australia. His research interests include computer vision and deep learning, with focus on low-shot classification, long-tail classification, and visual reasoning. His research works have been published on main computer vision journals and conferences, such as TPAMI, IJCV, TIP, CVPR, and AAAI.

Heng Tao Shen (Fellow, ACM) received the B.Sc. (First Class Hons.) and Ph.D. degrees in computer science from the Department of Computer Science at National University of Singapore in 2000 and 2004 respectively. He is currently a Professor, the Dean of School of Computer Science and Engineering, the Executive Dean of Artificial Intelligence Research Institute, and the Director of Center for Future Media at University of Electronic Science and Technology of China. His current research interests include multimedia search, computer vision, artificial intelligence, and big data management. He has published over 250 peer-reviewed papers, and received 7 best paper awards from international conferences, including the Best Paper Award from ACM Multimedia 2017 and Best Paper Award-Honourable Mention from ACM SIGIR 2017. He has served as General Co-chair for ACM Multimedia 2021 and Program Committee Co-Chair for ACM Multimedia 2015, and is an Associate Editor of ACM Transactions of Data Science, IEEE Transactions on Image Processing, IEEE Transactions on Multimedia, and IEEE Transactions on Knowledge and Data Engineering.

Nicu Sebe (Senior Member, IEEE) is Professor with University of Trento, Italy, leading the research in the areas of multimedia information retrieval and human behavior understanding. He was the General Co-Chair of the IEEE FG Conference 2008 and ACM Multimedia 2013, and the Program Chair of the International Conference on Image and Video Retrieval in 2007 and 2010, ACM Multimedia 2007 and 2011. He was the Program Chair of ICCV 2017 and ECCV 2016, and a General Chair of ACM ICMR 2017. He is a fellow of IAPR.

Xuelong Li (M’02-SM’07-F’12) is a full professor with School of Computer Science and Center for OPTical IMagery Analysis and Learning (OPTIMAL), Northwestern Polytechnical University, Xi’an 710072, P.R. China.
