Filling in the Flyover Zone: High Phosphorus in Midwestern (USA) Reservoirs Results in High Phytoplankton Biomass but Not High Primary Productivity

Erin L. Petty, Daniel V. Obrecht and Rebecca L. North*

MU Limnology Laboratory, School of Natural Resources, College of Food, Agriculture, and Natural Resources, University of Missouri, Columbia, MO, United States

In lakes and reservoirs, climate change increases surface water temperatures, promotes thermal stability, and decreases hypolimnetic oxygen. Increased anthropogenic land-use and precipitation enhance nutrient and sediment supply. Together, these effects alter the light and nutrient dynamics constraining phytoplankton biomass and productivity. Given that lake and reservoir processes differ, and that globally, reservoir numbers are increasing to meet water demands, reservoir-centric studies remain underrepresented. In the agricultural Midwest (United States), ubiquitous reservoirs experience eutrophication and hypolimnetic anoxia. Here, we explore influences of eutrophication and land-use on the proximate light and nutrient status of phytoplankton communities in 32 Missouri reservoirs. Light and nutrient status indicators include mixed layer irradiance, phosphorus (P) and nitrogen (N) stoichiometry/debts, photosynthetic efficiency, and photosynthetic-irradiance parameters. Contributing to the ongoing P vs. N and P management debate, we evaluate if phytoplankton biomass and productivity are constrained by light, P, N, or a combination thereof, across gradients of trophic status and land-use during two contrasting wet and dry summers. Despite agricultural prevalence, P-deficiency is more prominent than either N- or light-deficiency. In 2018, ∼46% of samples were P-deficient with ∼36% indicating neither light nor nutrient deficiency. Gross primary productivity per unit chlorophyll-a (GPP\textsuperscript{B}) demonstrates negative relationships with nutrients, biomass, and turbidity, and positive relationships with light availability. GPP\textsuperscript{B} is highest in oligotrophic reservoirs where light utilization efficiency is also highest. Overall, phytoplankton biomass and productivity appear constrained by P and light, respectively. If Midwestern reservoirs are precursors of future inland waters affected by climate change and eutrophication, our crystal ball indicates that both P and light will be important regulators of phytoplankton dynamics and subsequent water quality.

Keywords: nitrogen, phosphorus, trophic status, eutrophication, phytoplankton, climate change, nutrients, light
INTRODUCTION

Inland freshwaters, such as lakes and reservoirs, are viewed as valuable and sensitive sentinels of climatic change (Williamson et al., 2009a). Climate forcing is primarily driven by altered patterns of incident solar radiation, air temperature, and precipitation (Williamson et al., 2009b). In response to increasing air temperatures, there is global evidence that lakes are warming (Schmid et al., 2014; O’Reilly et al., 2015). While exact responses vary across systems (O’Reilly et al., 2015; Woolway and Merchant, 2017), long-term incremental increases in global air temperatures are promoting earlier, stronger, and extended stratification in many inland surface waters (Woolway and Merchant, 2019). Climate-induced alterations to vertical mixing and stratification are also expected to change in-lake productivity (O’Reilly et al., 2003; O’Beirne et al., 2017), impacting light and nutrient dynamics (Verburg and Hecky, 2009; Williamson et al., 2009b).

Climate and anthropogenic activity mutually contribute to intensify freshwater eutrophication (Jepesen et al., 2010). Watershed land-use and regional precipitation patterns affect the supply of nutrients and sediment transported to and transformed within- lakes and reservoirs (Hayes et al., 2015). Agriculture and urbanization have drastically increased proportions of the bioavailable macronutrients, phosphorus (P) and nitrogen (N), on the landscape and within aquatic ecosystems (Bennett et al., 2001; Galloway et al., 2008; Howarth et al., 2012). Watersheds dominated by cropland agriculture typically export nutrients and sediment to lakes and reservoirs at higher rates and concentrations than do undisturbed and/or forested watersheds (Knowlton and Jones, 1995; Knoll et al., 2003). In the central US, more intense rainfall events as a result of climate-induced changes in precipitation are expected to enhance episodic pulses of nutrients and sediment in surface runoff. These interactions influence aquatic light conditions and increase the quantity of P and N available to phytoplankton communities in lakes and reservoirs (Paelr and Scott, 2010).

Variations in light availability as well as P and N supply can impact the light and nutrient status of phytoplankton communities where a balance of light and nutrients is needed for photosynthesis, nutrient uptake, and assimilation. As such, deficiencies in light and/or nutrients play a key role in controlling phytoplankton community structure, growth, and productivity (Titman, 1976). The relative importance of P and N as controls in freshwater ecosystems, however, has been contested for decades (Schindler, 1977; Elser et al., 1990; Schindler et al., 2008; Paerl et al., 2016). The traditional paradigm designates P as the single primary macronutrient controlling phytoplankton growth and productivity in temperate freshwater lakes (Schindler, 1974, 1977; Guildford and Hecky, 2000), but there is evidence that N, too, has a role to play (Morris and Lewis, 1988; Elser et al., 1990; Lewis and Wurtsbaugh, 2008; Abell et al., 2008b). Numerous inland studies even offer evidence of simultaneous control by P and N (Elser et al., 2007; North et al., 2007; Sterner, 2008; Rowland et al., 2019) and/or light (Millard et al., 1996; Guildford et al., 2000; Knowlton and Jones, 2000; Dubourg et al., 2015).

Lakes and reservoirs were once considered synonymous (Hutchinson, 1957). Contemporary limnology, however, has shown that even though they possess many shared characteristics, reservoir processes sometimes differ from those of natural lakes (Kimmel and Groeger, 1984; Hayes et al., 2017). For example, reservoirs tend to have larger watersheds with greater contributions of nutrients and sediment that promote increased productivity and reduced water clarity (Hayes et al., 2017). Reservoir-centric studies, however, are underrepresented relative to natural lake studies. As global reservoir and dam construction intensify to meet growing water demands (Zarfl et al., 2015), it may become increasingly important that we equally understand the processes of both lakes and reservoirs, particularly as they relate to climate change and eutrophication. Being the primary lentic habitat in the central US (Thornton, 1990), ubiquitous Midwestern reservoirs may serve as climate analogs for future aquatic ecosystems. High eutrophication rates in the agriculturally dominated Midwest (Mitsch et al., 2001; Jones et al., 2008a) make these reservoirs precursors of future surface water quality, as ~94% of reservoirs in the study region are classified as mesotrophic, eutrophic, or hypertrophic (Jones et al., 2008b). Moreover, since Midwestern reservoirs regularly experience hypolimnetic anoxia during summer stratification (Jones et al., 2011), they may also forewarn how future light and nutrient dynamics will affect phytoplankton biomass and primary productivity.

Here, we explore influences of climate, eutrophication, and land-use on the proximate light and nutrient status of phytoplankton communities in 32 Midwestern reservoirs. By evaluating general indicators of water quality and proximate physiological deficiencies in the phytoplankton communities, we determine if chlorophyll-a (chl-a), as a proxy for phytoplankton biomass, and primary productivity are constrained by light, P, N, or a combination thereof. We explore these constraints across gradients of trophic status and land-use, which reflect gradients in nutrient concentrations as well as ambient light environments, during the climatically contrasting summers of 2017 (wet) and 2018 (dry). Decades of previous work on Midwestern reservoirs utilized Liebig’s Law of the Minimum (Von Liebig, 1840) to identify important empirical relationships between concentrations of chl-a, and P (r² = 0.83) and N (r² = 0.78; Jones et al., 2008b). Our study applies the concept of Blackman limitation (Blackman, 1905), or rate limitation, to describe the condition(s) by which phytoplankton growth, productivity, and photosynthetic responses are constrained by resource availability. We describe limitation in terms of proximate deficiency (Tyrrell, 1999), which considers the phytoplankton communities’ instantaneous responses to nutrients and/or light. We also invoke the term co-deficiency to describe simultaneous constraint by more than one resource (Saito et al., 2008), whether that be by light and a nutrient or by multiple nutrients (Healey, 1983). Building off previously elucidated relationships (Jones et al., 2008b), we predict that light and both P and N will serve as proximate controls of phytoplankton communities regardless of climatic year. Light deficiency will occur in eutrophic and hypertrophic reservoirs and nutrient deficiency in oligotrophic reservoirs; culminating in the highest phytoplankton biomass and productivity in hypertrophic reservoirs.
FIGURE 1 | Map showing the 32 reservoir study sites located in Missouri, United States. Sites represent the trophic gradient demonstrated by reservoirs throughout the state from very low (~0.10 µmol L\(^{-1}\)) to very high (~4.40 µmol L\(^{-1}\)) epilimnetic total phosphorus concentrations. Symbols distinguish trophic status, where \(\bullet, \triangle, \bigcirc, \square\) represent oligo-, meso-, eu-, and hyper-trophic, respectively. All are warm monomictic, except for polymictic Niangua which is denoted as a eutrophic circle with a filled dot (*) in the center. Shading indicates the dominant land-use that has been generalized for each of the state’s major physiographic regions, with the north dominated by agriculture, the south largely forested, and mixed land cover in-between. Land-use specific to each reservoir’s watershed has been classified separately.

MATERIALS AND METHODS

Study Site Description

We sampled 32 mid-continental, mid-latitude manmade reservoirs in the summers of 2017 and 2018. The reservoirs are located across Missouri, a Midwestern state in the central US (Figure 1). Missouri is characterized by five main physiographic regions (Thom and Wilson, 1980), which correspond to a gradient in dominant land-use. Our study reservoirs span four of the five physiographic regions, representing the land-use and resultant trophic status gradients (Jones et al., 2008a,b), where five of the reservoirs are oligo-, 13 meso-, 12 eu-, and 2 hyper-trophic. Trophic classification is based on average total phosphorus (TP) concentrations during the 2-year summer sampling window (criteria from Jones et al., 2008b). The reservoirs were chosen to represent a range in nutrient concentrations, underwater light conditions, phytoplankton biomass, reservoir morphology, and watershed land-use. All are warm monomictic, except for Lake Niangua, which is a shallow (6.1 m maximum depth), polymictic reservoir (Supplementary Table 1).

Watershed land-use/land-cover (LULC) data was derived from the 2016 National Land Cover Database, a product of the Multi-Resolution Land Characteristics Consortium (Yang et al., 2018). We selected watershed boundaries of interest from the Missouri 2019 Lake Numeric Nutrient Criteria Watersheds dataset developed by the Missouri Department of Natural Resources (MDNR). Watersheds not included in this dataset were manually digitized using flow direction and

\(^{1}\)www.mrlc.gov

\(^{2}\)http://msdisweb.missouri.edu
flow accumulation grids generated from 10-m resolution digital elevation models in ESRI ArcGIS 10.5. We zonally tabulated LULC for each watershed in ArcGIS, and calculated LULC as percent developed, barren, forest, rangeland, wetland, and agriculture which also contained pasture and cropland subclasses. Watersheds were categorically generalized as either agriculture (pasture or cropland), forest, or mixed based on the dominant (>50%) LULC. When a watershed contained >50% agriculture, the watershed was specified as either ag-pasture or ag-crop to denote the subclass with the higher contribution. A mixed classification was assigned to watersheds with no single LULC greater than 50%. Barren (0–2%), rangeland (0–10%), wetland (0–3%), and developed (0–10%, except for four watersheds with 22–44%) were considered minor contributions to overall LULC and were not included as unique LULC categories.

Each year, we sampled the reservoirs 3–4 times between mid-May and mid-September during a period of established thermal stratification. Throughout these months, the climate across May and mid-September during a period of established thermal and were not included as unique LULC categories. May and mid-September during a period of established thermal

**Field Sampling**

Sampling occurred at maximum water depth near the dam of each reservoir. Secchi transparency depths were recorded. Photosynthetically active radiation (PAR) profiles were collected in 0.25-m increments using a cosine corrected underwater quantum sensor (LI-192, Li-Cor Biosciences, Lincoln, Nebraska, United States). The vertical attenuation coefficient (Kd) was calculated from the PAR profiles using the linear regression of the natural logarithm of irradiance to depth (Kirk, 2011). A Yellow Springs Instruments (Yellow Springs, Ohio, United States) EXO3 multi-parameter sonde was deployed to collect depth profiles (0.001 m resolution) of temperature (0.001°C resolution with an accuracy of ± 0.01°C) and dissolved oxygen (DO) measured with an optical sensor (0.01 mg L⁻¹ resolution with an accuracy of ±0.1 mg L⁻¹). Integrated epilimnetic whole water samples were collected via peristaltic pump from the surface to one meter above the thermocline, where the thermocline was defined in the field by vertical temperature gradients ≥1.0°C m⁻¹. Discrete hypolimnetic whole water samples were collected via Van Dorn sampler from one meter off bottom. During isothermal conditions (e.g., polymictic Lake Niangua), a single integrated sample was taken from the surface to one meter off bottom via peristaltic pump. All water samples were collected into acid-washed high-density polyethylene (HDPE) containers, placed in coolers, and returned to the University of Missouri Limnology Laboratory within 12-h of collection where they were then processed.

**Laboratory Analyses and Data Processing**

**Physical Parameters**

Maximum depth (Zmax) was based on records of dam height provided by MDNR. Water column mixing depth (Zmix) was determined using the “rLakeAnalyzer” R-package (Winslow et al., 2019) and reported as the depth from surface to the top of the metalimnion. Based on sampling date and latitude, daily incident irradiance was modeled in 1 min increments and scaled to PAR (µmol photons m⁻² s⁻¹) using the “phyttools” R-package (Silsbe and Malkin, 2015). We then calculated mean daily (24-h) incident irradiance (E₀), assuming cloud-free conditions. Following Guildford et al. (2000), we derived mean daily mixed layer irradiance (E24) from Kd, Zmix, and E₀:

\[
E_{24} = E_0 \times (1 - \exp(-1 \times K_d \times Z_{mix})) \times (K_d \times Z_{mix})^{-1} \tag{1}
\]

where E24 describes the amount of light experienced in the mixed layer by suspended phytoplankton over a 24-h period.

**Chemical Parameters**

Water samples were processed and analyzed for TP and total N (TN), total dissolved P (TDP) and N (TDN), dissolved reactive P (DRP), ammonium (NH₄⁺), nitrate (NO₃⁻), dissolved organic carbon (DOC), particulate N (PN), and particulate P (PP). TP and TN were pipetted directly into glass test tubes and refrigerated until analysis. All dissolved nutrient samples were filtered through glass-fiber filters (GFF, 0.7 µm pore). Filters for DOC filtrate were pre-combusted at 550°C for 4 h. Filtrate for TDP and TDN were refrigerated in glass test tubes, while DRP, NH₄⁺, NO₃⁻ and DOC samples were stored frozen in acid-washed HDPE bottles. PN and PP were captured on pre-combusted GFF filters (0.7 µm pore), dried, and stored with desiccant.

All P samples were analyzed spectrophotometrically using an ascorbic acid colorimetric method (APHA, 2017; 4500-P E). TP, TDP, and DRP were analyzed in triplicate; PP in duplicate. TP, TDP, and PP were digested prior to analysis following an ammonium peroxydisulfate method (APHA, 2017; 4500-P B). Detection limits for all P analyses are 0.03 µmol L⁻¹.

TN and TDN were analyzed in triplicate using the second derivative spectroscopy method (Crumpton et al., 1992). NH₄⁺ and NO₃⁻ were analyzed in duplicate on a Lachat QuikChem Flow Injection Analyzer (Hach, Loveland, Colorado, United States) using a Lachat method for NH₄⁺ (10-107-06-1-K) and a slightly modified Lachat method for NO₃⁻ (10-107-04-A/B/C). Detection limits were 2.50 µmol L⁻¹ for TN and TDN, 0.71 µmol L⁻¹ for NH₄⁺, and 0.36 µmol L⁻¹ for NO₃⁻. Dissolved organic nitrogen (DON) was calculated by difference from TDN, NH₄⁺, and NO₃⁻. PN was analyzed at the UC Davis Stable Isotope Facility using an Elementar Vario EL Cube or Micro Cube elemental analyzer (Elementar Analysensysteme GmbH, Hanau, Germany) interfaced to a PDZ Europa 20-20 isotope ratio mass spectrometer (Sercon Ltd., Cheshire, United Kingdom) with a detection limit of 0.7 µmol N.
Physical

- Maximum depth: $Z_{\text{max}}$ (meters)
- Mixing depth: $Z_{\text{mix}}$ (meters)
- Secchi disk depth: Secchi (meters)
- Photosynthetically active radiation: PAR ($\mu$mol photons m$^{-2}$ sec$^{-1}$)
- Vertical light attenuation coefficient: $K_d$ (meters$^{-1}$)
- Mean daily incident irradiance: $E_0$ ($\mu$mol photons m$^{-2}$ sec$^{-1}$)
- Mean daily mixed layer irradiance: $E_{24}$ ($\mu$mol photons m$^{-2}$ sec$^{-1}$)

Chemical

- Total phosphorus: TP ($\mu$mol L$^{-1}$)
- Total dissolved phosphorus: TDP ($\mu$mol L$^{-1}$)
- Dissolved reactive phosphorus: DRP ($\mu$mol L$^{-1}$)
- Particulate phosphorus: PP ($\mu$mol L$^{-1}$)
- Total nitrogen: TN ($\mu$mol L$^{-1}$)
- Total dissolved nitrogen: TDN ($\mu$mol L$^{-1}$)
- Ammonium: NH$_4^+$ ($\mu$mol L$^{-1}$)
- Nitrate: NO$_3^-$ ($\mu$mol L$^{-1}$)
- Dissolved organic nitrogen: DON ($\mu$mol L$^{-1}$)
- Particulate nitrogen: PN ($\mu$mol L$^{-1}$)
- Dissolved organic carbon: DOC ($\mu$mol L$^{-1}$)
- Total suspended solids: TSS ($\mu$g L$^{-1}$)
- Particulate organic matter: POM ($\mu$g L$^{-1}$)
- Particulate inorganic matter: PIM ($\mu$g L$^{-1}$)

Biological

- Chlorophyll-$a$: $\text{chl}_a$ ($\mu$g L$^{-1}$)
- Particulate organic carbon: POC ($\mu$mol L$^{-1}$)
- Areal pigment absorption coefficient: $a_0$ (m$^{-2}$ mg chl$^{-1}$)

Nutrient status

- Particulate organic carbon to chlorophyll-$a$ ratio: POC:chl$_a$ ($\mu$mol C $\mu$g chl$^{-1}$)
- Total nitrogen to total phosphorus ratio: TN:TP (Molar ratio)
- Particulate organic carbon to particulate phosphorus ratio: POC:PP (Molar ratio)
- Particulate nitrogen to particulate phosphorus ratio: PN:PP (Molar ratio)
- Particulate organic carbon to particulate nitrogen ratio: POC:PN (Molar ratio)
- Indicator of phosphorus uptake: P -debt ($\mu$mol P $\mu$g chl$^{-1}$)
- Indicator of ammonium uptake: NH$_4^+$ -debt ($\mu$mol N $\mu$g chl$^{-1}$)
- Indicator of nitrate uptake: NO$_3^-$ -debt ($\mu$mol N $\mu$g chl$^{-1}$)

P-E parameters

- Maximum quantum yield of PSII for photochemistry: $\Phi_{\text{PSII}}$ (Unitless)
- Light utilization efficiency (light limited slope of P-E curve): $\alpha$ (Photons reemitted photons absorbed$^{-1}$/$\mu$mol photons m$^{-2}$ sec$^{-1}$)
- Light utilization efficiency normalized to chlorophyll-$a$: $\alpha^*$ (Photons reemitted photons absorbed$^{-1}$/$\mu$mol photons (mg chl$^{-1}$) m sec$^{-1}$)
- Light saturation parameter: $E_{s*}$ ($\mu$mol photons m$^{-2}$ sec$^{-1}$)
- Light saturation parameter normalized to chlorophyll-$a$: $E_{s*}^\text{chl}$ ($\mu$mol photons (mg chl$^{-1}$) m sec$^{-1}$)
- Maximum relative electron transport rate through PSII: $r\text{ETR}_{\text{max}}$ (Photons reemitted photons absorbed$^{-1}$)
- Light-deficiency threshold: $E_{\text{E}_{24}}/E_{s*}$ (Unitless)
- Daily gross primary productivity rate: GPP (mmol O$_2$ m$^{-2}$ day$^{-1}$)
- Daily gross primary productivity rate normalized to chl-$a$: GPP$^\text{chl}$ (mmol O$_2$ (mg chl$^{-1}$) m day$^{-1}$)

Definitions, abbreviations, and units describing physical, chemical, and biological parameters.

We analyzed DOC in duplicate following a combustion-infrared method (APHA, 2017; 5310 B) with a Shimadzu total organic carbon analyzer (TOC-VCPH, Shimadzu Scientific Instruments, Columbia, Maryland, United States). The detection limit for DOC was 16.7 $\mu$mol L$^{-1}$.

Seston was collected on Whatman 934-AH filters (1.5 $\mu$m pore) in duplicate and analyzed for total suspended solids (TSS) using a standard tared-weight method (APHA, 2017; 2540-D E) with a detection limit of 0.1 mg L$^{-1}$. Dried (105°C) and weighed filters were placed in a muffle furnace at 550°C for 20 min to burn off particulate organic matter (POM). Filters were weighed again to determine particulate inorganic matter (PIM). POM was calculated by difference from TSS and PIM.

Biological Parameters

Chla concentrations (proxy for phytoplankton biomass) were measured on whole water samples filtered onto 0.7 $\mu$m GFF filters which were immediately frozen and stored with desiccant. After ethanol extraction and pheophytin acid-correction, chla was analyzed on a Turner Design fluorometer (TD700, San Diego, California, United States).

We calculated the molar ratios of particulate organic carbon to particulate nitrogen (POC:PN) and particulate organic carbon to particulate phosphorus (POC:PP), as well as the ratio of total phosphorus (TP) to total nitrogen (TN), to assess potential nutrient limitation. We calculated the daily gross primary productivity rate (GPP), normalized to chlorophyll-$a$ (GPP$^\text{chl}$), using the following equation:

$$GPP^\text{chl} = \frac{\text{GPP}}{\text{chl}_a}$$
Jose, California, United States; Knowlton, 1984; Sartory and Grobbelaar, 1984). The detection limit was 0.09 μg L$^{-1}$.

Particulate organic carbon (POC) samples were collected on pre-combusted GFF filters (0.7 μm pore). Inorganic carbonates were removed from samples following a modified fumigation method based on Brodie et al. (2011) wherein filters were continuously subjected to concentrated 37% hydrochloric acid fumes for 4 h. After fumigation, samples were dried at 55–60°C and stored with desiccant. POC was analyzed at the UC Davis Stable Isotope Facility using an Elementar Vario El Cube or Micro Cube elemental analyzer (Elementar Analysensysteme GmbH, Hanau, Germany) interfaced to a PDZ Europa 20–60 isotope ratio mass spectrometer (Sercon Ltd., Cheshire, United Kingdom) with a detection limit of 1.7 μmol C.

The quantitative filter technique (Tassan and Ferrari, 1995) was used to determine the areal pigment absorption coefficient ($a_{ph}$), which provides an estimate of cross-sectional light absorption via chl$a$ for photochemistry and photosynthesis. We passed whole water samples through GFF filters (pore size 0.7 μm) that were immediately placed in foil-wrapped petri dishes to limit light exposure and frozen. Absorbance was measured before and after epigmentation via sodium hypochlorite solution (4–5% active chlorine) on a scanning spectrophotometer (Agilent Cary60 UV/VIS, Santa Clara, California, United States) in 1 nm increments from wavelengths 350–750 nm. We calculated $a_{ph}$ based on Silsbe et al. (2012):

$$a_{ph} = 2.303 \times (A_P - A_{NAP}) \times \beta^{-1} \times (V_f/A_f)^{-1}$$

where $A_P$ and $A_{NAP}$ are sestonic absorption before and after epigmentation, respectively; $\beta$, equaling 2, is the path-length amplification factor adjusting for absorption differences between filter and water; $V_f/A_f$ is the ratio of filter volume to circumferential area of filtered particulates.

**Light and Nutrient Status Indicators**

Phytoplankton light and nutrient status were assessed using a suite of deficiency indicators, which included $\bar{E}_{24}^{24}$, $\bar{E}_{24}^{24}/E_k$, POC:chl$a$; P-, NH$_4^+$-N, and NO$_3^-$-N debts; stoichiometric nutrient ratios (TN:TP, POC:PP, PN:PP, POC:PN); and photosynthetic efficiency experiments. These indicators have previously established, literature-supported thresholds for estimating proximate deficiencies of light, P, and N (Table 2; Healey and Hendzel, 1979; Guildford and Hecky, 2000). Thresholds based on the work of Healey and Hendzel (1979) were applied to measurements of P and NH$_4^+$-N debt, as well as to POC:PP, PN:PP, POC:PN, and POC:chl$a$. These thresholds were developed on laboratory culture experiments (Healey and Hendzel, 1979), but have been successfully applied across a diverse range of lake systems worldwide (e.g., Guildford et al., 2000; North et al., 2008; Dubourg et al., 2015).

**Light deficiency**

Our light deficiency thresholds ($\bar{E}_{24}^{24}$, $\bar{E}_{24}^{24}/E_k$) were developed on a turbid Canadian reservoir where the onset of P-deficiency occurred when $E_{24}$ was between 41.7 and 58.3 μmol photon m$^{-2}$ s$^{-1}$ (Hecky and Guildford, 1984). Knowlton and Jones (1996), who focused on the turbid Missouri reservoir- Mark Twain, as well as Millard et al. (1996) who worked on Lake Ontario, suggested that co-limitation by light and nutrients could occur at irradiances ≤ 69.4 μmol photon m$^{-2}$ s$^{-1}$. This irradiance threshold has been supported in other applications of shallow, turbid inland waters (Schallenberg and Burns, 2004). We have, therefore, adopted a $E_{24}$ threshold of 69.4 μmol photon m$^{-2}$ s$^{-1}$ to represent moderate light-deficiency and the Hecky and Guildford (1984) threshold of 41.7 to represent extreme light-deficiency (Table 2).

We also applied the ratio of $E_{24}/E_k$ to assess light-deficiency, where $E_{24}$ represents mean daily mixed layer irradiance and $E_k$, the LC-derived light saturation parameter (details below). The threshold for $E_{24}/E_k$ light-deficiency is one (Table 2). When $E_{24} > E_k$, there is theoretically enough light for photosynthesis. Alternatively, when $E_{24} < E_k$, phytoplankton may experience light-deficient conditions (Hecky and Guildford, 1984).

**Nutrient deficiency**

Nutrient debt experiments based on Healey (1977) were conducted to assess nutrient deficiency. In the laboratory, one L subsamples of epilimnetic whole water were placed in acid-washed cubitainers and spiked with ~5 μM of KH$_2$PO$_4$, NH$_4$Cl, or KNO$_3$. The four treatments (control receiving no nutrient addition, +P, +NH$_4^+$, +NO$_3^-$) were incubated in an environmental chamber for 18–24 h under darkened conditions (0.001–0.008 μmol photons m$^{-2}$ s$^{-1}$) at average ambient epilimnetic water temperatures (23–30°C). Samples for DRP, NH$_4^+$, and NO$_3^-$ were collected from the +P, +NH$_4^+$, and +NO$_3^-$ treatments, respectively, before and after incubation. DRP, NH$_4^+$, and NO$_3^-$ samples were also collected from each control treatment. P debt, NH$_4^+$-N debt, and NO$_3^-$-N debt, as indicators of nutrient uptake, were calculated as the change in nutrient concentration per unit of chl$a$ before and after incubation.

We complemented the Healey and Hendzel (1979) nutrient debts with additional photosynthetic efficiency experiments.

| Limiting factor | Indicator | Deficient | Moderately deficient | Extremely deficient |
|-----------------|-----------|-----------|----------------------|---------------------|
| Light           | $E_{24}/E_k$ | <1        | <69.4                | <41.7               |
| P               | $E_{24}$ | >0.075    | >129                 | >258                |
| POC:PP          | >22       | >50       |                      |                     |
| PN:PP           | >20       | >50       |                      |                     |
| TN:TP           | >0.15     | >4.2      | >8.3                 | >14.6               |
| N or P          | >0.15     | >4.2      | >8.3                 |                     |
| POC:PN          | >0.15     | >4.2      | >8.3                 |                     |
| TN:TP           | >20       | 20–50     |                      |                     |

Most indicator values are from Guildford and Hecky (2000); $E_{24}$ and $E_k$ are based on Hecky and Guildford (1984) and Knowlton and Jones (2000); and P debt, POC:PP, NH$_4^+$-N debt, POC:PN, and POC:chl$a$ on Healey and Hendzel (1979). See Table 1 for parameter definitions, abbreviations, and units.
These experiments assess phytoplankton physiological response to nutrient additions and provide additional evidence of nutrient deficiency. Nutrient additions and incubations followed the same protocol as the debt experiments described above. Following incubation, maximum quantum yields of photosystem II (φPSII) of each treatment was measured as described below. Significant increases in φPSII from control to nutrient addition treatment suggested deficiency of that nutrient.

P-E Parameters
We measured φPSII and rapid light curves (LC) to evaluate the phytoplankton’s capability to absorb and utilize light energy for photosynthesis via PSII. We used the empirical optimum value of ~0.65 (Kromkamp et al., 2008) to assess overall phytoplankton stress. Following a 30-min dark adaptation period, both φPSII and LCs were measured from whole water samples in triplicate with a Water-Pulse Amplitude Modulated (Water-PAM) Fluorometer (Heinz Walz GmbH, Effeltrich, Germany) interfaced to WinControl software (version 3.26). We corrected for non-algal background fluorescence with sample filtrate that had been passed through a 0.2 μm pore GFF filter. LCs were measured in nine 1-min intervals wherein light intensity steadily increased from 21 to 1,420 μmol photons m⁻² s⁻¹. Photosynthetic-irradiance (P-E) parameters describing light utilization efficiency (α) and light saturation (Eₛ) were derived by fitting each LC to a normalized irradiance model (Webb et al., 1974) in the “phytotools” R-package (Silsbe and Malkin, 2015). The maximum relative electron transport rate through PSII (rETRmax) was then calculated as the product of α and Eₛ. For comparison across systems, α and Eₛ were normalized to chla (αB, EₛB).

Gross Primary Productivity
Areal rates of gross primary productivity (GPP) of the phytoplankton communities were estimated based on the Fee (1990) primary production model. With the “phytoprod” function of the “phytotools” R-package (Silsbe and Malkin, 2015), we calculated GPP from α, Eₛ, chla, aₙ, Kₐ, and Eₛ. Final units of mol O₂ m⁻² day⁻¹ were reached by multiplying the “phytoprod” output by the molecular weight of O₂ as well as the quantum yield of O₂ evolution, which we assume is 0.25 mol O₂ [mol e⁻]⁻¹. For comparison across systems, GPP was normalized to chla (GPPB).

Statistical Analyses
All data were assessed for normality using the Shapiro-Wilk test (p < 0.05). If we accepted the null hypothesis of the Shapiro-Wilk test (p < 0.05), data were transformed accordingly (e.g., common log, square root, reciprocal), whenever possible, to achieve normality prior to any statistical analysis. If we rejected the null hypothesis of the Shapiro-Wilk test (p > 0.05), data were assumed normal and no transformations applied.

To explore relationships between continuous parametric variables, we used Pearson’s correlation coefficients (r). To assess differences across temporal gradients (between years and/or sampling events), as well as across the trophic and land-use gradient for each reservoir, we ran linear mixed effect (LME) models with the “nlme” R-package (Pinheiro et al., 2020). For parameters collected in both 2017 and 2018, we used the following model structure:

\[ Y_i = \beta_0 + \beta_1 \text{Year} + \beta_2 \text{SamplingEvent} + \beta_3 \text{Year} \times \text{SamplingEvent} + \beta_4 \text{TrophicStatus} + \beta_5 \text{LandUse} + \text{Reservoir} + \epsilon_i \]

where \( Y_i \) was the normally distributed parameter \( Y \) at reservoir \( i \), while Year (2017, 2018), SamplingEvent (1–4), TrophicStatus (oligotrophic to hypertrophic), and LandUse (forested, mixed, ag-pasture/crop) were fixed effects. Reservoir was a random effect that created a new baseline for each sampling location. Random effects and the residual error were assumed to be drawn from a normal distribution. A simplified model lacking Year and the interaction term (Year × SamplingEvent) was applied for parameters collected in a single year. Each LME was subjected to an analysis of variance (ANOVA). If the ANOVA identified statistically significant effects in the LME (p < 0.05), we conducted a Tukey’s Honest Significant Difference post-hoc test to compare factor levels for significance. All post-hoc results are indicated by lowercase letters on figures and in tables, unless otherwise noted. Different lowercase letters indicate significant differences between factor levels. Letters are ordered alphabetically and indicate trend direction where, for example, “a” represents the lowest and “d” represents the highest mean.

To assess significant differences across sampling events, trophic status, and watershed land-use for the nutrient debt experiments, we conducted non-parametric Kruskal-Wallis one-way ANOVAs. If an ANOVA tested significant (p < 0.05), a Dunn’s multiple comparisons post-hoc test was implemented to identify significant differences between factor levels. We also used one-way ANOVAs to test for significant differences among treatments for each φPSII experiment. If significant (p < 0.05), a 2-sided Dunnett-test (pairwise comparison) was conducted to identify significant positive responses to nutrient additions of P, NH₄⁺, NO₃⁻, and P+NH₄⁺ relative to untreated control treatments.

RESULTS
Northern Missouri is 58% agriculture while the south is 61% forested (Figure 1 and Supplementary Table 1). TP concentrations are correlated with forest (p < 0.001, r = −0.65), ag-crop (p < 0.001, r = 0.65), and ag-pasture (p < 0.001, r = 0.31) percent land-cover. As percent forest increases, we observe lower TP and more oligo- and meso-trophic systems. Alternatively, as percent agriculture increases, we observe higher TP and more eu- and hyper-trophic systems.

Physical Parameters
Missouri reservoirs are relatively shallow systems where Zmax ranges from 4.6 to 49.1 m (Table 3), with 63% of our study reservoirs <20 m and only 9% >40 m. Mean Zmix was ~27–30% of the water column in oligo-, meso-, and eu-trophic reservoirs, and 51% in hypertrophic reservoirs (Tables 3, 4). There is a negative correlation between Zmax and trophic status (p < 0.001, r = −0.47), wherein shallower reservoirs are hypertrophic and deeper reservoirs are oligotrophic. Similarly, Zmix was significantly shallower in hypertrophic than oligotrophic systems.

Shown are the arithmetic means and ranges (minimum-maximum) of n samples grouped along the trophic gradient. See Table 1 for parameter definitions, abbreviations, and units.

(Table 5). Hypolimnetic anoxia is common in Missouri reservoirs during summer stratification (Jones et al., 2011). We observed this in both summers, wherein every warm monomictic reservoir (n = 31) experienced hypolimnetic anoxia with DO concentrations < 0.5 mg L\(^{-1}\). Across these 31 reservoirs, water columns were 27–87% anoxic, with the mean water column ~65% anoxic.

The light environment in the reservoirs differed significantly from 2017 to 2018, although Z_{mix} did not. Water clarity was highest in oligotrophic reservoirs during the drier sampling year (2018). Across all reservoirs, Secchi depths were significantly deeper and K_{sp} were significantly smaller during the drier year (Table 5). In oligotrophic systems, Secchi depths were ~6–7× deeper and K_{sp}s were ~73–82% smaller than in hypertrophic systems. Compared to 2017, TSS in 2018 was 25% lower in oligo- and ~10% lower in meso- and eu- trophic reservoirs. These relationships fall apart in hypertrophic systems where we saw no significant differences (p > 0.05) in Secchi, K_{sp}, nor TSS from 2017 to 2018 (Table 4).

Light Deficiency

Light deficiency was not prominent during the summers of 2017 and 2018. Across both years, E_{24} trophic means ranged from 65.9 to 227.3 \(\mu\)mol photons m\(^{-2}\) s\(^{-1}\) and while there were no significant differences between trophic status nor wet and dry years, E_{24} was lower during the wetter year and decreased from oligo- to hyper- trophic (Figure 2). Only 6% (2017) and 3% (2018) of individual samples were below the 41.7 \(\mu\)mol photons m\(^{-2}\) s\(^{-1}\) threshold for extreme light-deficiency (Table 2 and Figure 2). No reservoir below the extreme-light-deficiency threshold in 2017 fell below it again in 2018. Only the mean E_{24} for the 2017 hypertrophic reservoirs (65.9 \(\mu\)mol photons m\(^{-2}\) s\(^{-1}\)) was below the 69.4 \(\mu\)mol photons m\(^{-2}\) s\(^{-1}\) moderate threshold for light-deficiency (Table 4 and Figure 2). Approximately 27% of all sampling events were less than the moderate threshold in 2017 compared to ~19% in 2018 (Figure 2). Of the eight reservoirs below the threshold in 2017, nine also fell below during at least one sampling event in 2018. We found significant differences between E_{24} and sampling event, as well as land-use. E_{24} was significantly higher during the May/June sampling event, and in forested watersheds, than during the August/September sampling event or in ag-pasture watersheds (Table 5).

Relative to the light saturation parameter (E_{S}), the ratio of E_{24}/E_{S} indicates that light-deficiency dominated in these systems. Summer means for E_{24}/E_{S} across the trophic groupings ranged from 0.28 to 0.80 and were below the light-deficiency threshold of one (Table 4). Only calculated for the reservoirs sampled in 2018, it indicates that the demand for light exceeded the supply (ratio < 1) for 92% of sampling events; 75% in oligo-, 91% in meso-, 97% in eu-, and 100% in hyper- trophic reservoirs. All 29 of the reservoirs, regardless of trophic status, were light-deficient by this metric at least once during the 2018 season. All sampling events that were below the E_{24} moderate deficiency threshold in 2018 were also deemed light deficient by the E_{24}/E_{S} threshold. We found no evidence of photoacclimation (MacIntyre et al., 2002) as indicated by positive, significant relationships between POC and chl\(\alpha\) in 2017 (p < 0.001, r = 0.78) and 2018 (p < 0.001, r = 0.90). Peak POC:chl\(\alpha\) ratios occurred above the light threshold, when E_{24} was ~50–150 \(\mu\)mol photons m\(^{-2}\) sec\(^{-1}\), indicating nutrient deficiency.

Chemical and Biological Parameters

Nutrient concentrations were positively related to trophic status for most forms of P and N (TDP, DRP, PP, TN, TDN, DON, PN). Trophic mean concentrations of TP and DOC were higher during the wetter than the drier year (Table 5), except for in hypertrophic reservoirs where the relationship weakened (Table 4). Similarly, trophic mean particulate nutrient concentrations (i.e., PP, PN, POC) were also significantly higher during the wetter year (Table 5), barring the hypertrophic reservoirs.

From oligo- to hyper- trophic, mean epilimnetic TP concentrations ranged from 0.23 to 3.21 \(\mu\)mol L\(^{-1}\). Across the trophic gradient, TP largely consisted of PP wherein TP concentrations generally increased with increasing trophic status. With the trophic gradient, mean epilimnetic DRP constituted ~30–39% of TN in oligo-, meso-, and eu- trophic and 61% of TN in hypertrophic reservoirs. DON represented the largest fraction of epilimnetic TDN, with NO\(_3\) + NH\(_4\) + accounting for ~18% of epilimnetic TDN (Table 4). In 2018, mean epilimnetic NO\(_3\) was 1.75 \(\mu\)mol L\(^{-1}\), while NH\(_4\) + was 0.89 \(\mu\)mol L\(^{-1}\) (Table 6). The majority of epilimnetic NH\(_4\) + (68%) and NO\(_3\) (79%) were below detection. In ag-crop

Numbers in superscript indicate n values that differed from those reported in the column headers. An asterisk (*) is used when values are below detection limit. See Table 1 for parameter definitions, abbreviations, and units. See Table 6 for epitomically dissolved nutrient concentrations (TDN, TDN, NO$_3^-$, NO$_2^-$, DON).

washes, NO$_3^-$ was higher than NH$_4^+$ concentrations, whereas in forested, mixed, and ag-pasture reservoirs, NH$_4^+$ was higher than NO$_3^-$. Hypertrophic reservoirs also have more NH$_4^+$ relative to NO$_3^-$ compared to oligo-, meso-, and eutrophic reservoirs.

Mean hypolimnetic TDP, TDN, NO$_3^-$, and NH$_4^+$ were consistently higher than epilimnetic concentrations across the trophic gradient. Hypolimnetic DRP was not measured due to interference with presumably high iron concentrations. Mean hypolimnetic TDP was 1.2–1.7× higher than epilimnetic concentrations in oligo- and hyper-trophic systems, and 5.3–5.8× higher in meso- and eutrophic systems. Hypolimnetic NO$_3^-$ was 2–2.5× higher than epilimnetic NO$_3^-$ in eu- and hyper-trophic systems, and 13–15× higher than epilimnetic NO$_3^-$ in meso- and oligo-trophic systems. In contrast, hypolimnetic NH$_4^+$ was 32 (oligo-), 88 (meso-), 90 (eu-), and 78 (hyper- trophic)× higher than epilimnetic NH$_4^+$ concentrations. Hypolimnions contained ~2, 14, 8, and 277× more NH$_4^+$ than NO$_3^-$ in oligo-, meso-, eu-, and hyper-trophic systems, respectively (Table 6). TSS was dominated by POM (~60–69% in 2017 and 51–80% in 2018; Table 4). PIM only exceeded POM in ~15% of samples each year.

Both chla and POC serve as proxies for phytoplankton biomass. There were increasingly higher chla concentrations with increasing trophic status (Table 4 and Figure 3A) and higher chla trophic means in the wetter year. Reservoirs of forested and ag-pasture watersheds had the lowest and highest chla concentrations, respectively (Table 5).

**Nutrient Status**

Physiological indicators suggest that P-deficiency is prevalent in Missouri reservoirs (Figure 4). TN:TP ratios favored P-deficiency in both years (Table 4) with only 2% of samples indicating N-deficiency. TN:TP ratios were significantly higher in the drier year (2018) than the wetter year (2017; Tables 3, 5). Exceedance of the P-deficiency thresholds occurred in 83% of POC:PP and 65% of PN:PP samples (Tables 2, 4 and Figures 4A, B) with no significant differences between wet and dry years (Table 5). P debt results also support P-deficiency, with 7% of the samples exceeding the threshold in 2018 (Table 4 and Figure 4C). Only 11% of PH$_{PSII}$ P-addition experiments exhibited positive increases in PH$_{PSII}$ relative to the controls (Figure 4D and Supplementary Table 2).
### TABLE 5 | Linear mixed effect (LME) model output for physical, chemical, biological, nutrient status, and photosynthesis-irradiance (P-E) parameters.

| Fixed effect | F-value | p-value | Year 2017 | Year 2018 | Sampling event | Trophic status | Land-use |
|--------------|---------|---------|-----------|-----------|----------------|----------------|----------|
| **Physical** |         |         | 1 | 2 | 3 | 4 | O | M | E | H | F | Mix | Ag-P | Ag-C |

(Continued)
N-deficiency is not common in Missouri reservoirs (Figure 5). The POC:PN ratio, which was the only N-indicator applied in both years, showed no difference between 2017 and 2018 (Table 2) and only 35% of samples were above the N-deficiency threshold (Table 2, Figure 5A, and Supplementary Table 2). N debts and $\phi_{PSII}$ N-addition experiments provided little support for N-deficiency (Tables 4, 6, 7, Figure 5, and Supplementary Table 2).

Missouri reservoirs are primarily P-deficient. When plotted on a coordinate plane, the P debt and NH$_4^+$-N debt thresholds create four quadrants wherein we can estimate N-only deficiency (quadrant 1), NP co-deficiency (quadrant 2), P-only deficiency (quadrant 3) and sufficiency of both N and P (quadrant 4; Figure 6). None of the phytoplankton communities indicated N-only deficiency (quadrant 1) and only 8% fell in quadrant 2 suggesting NP co-deficiency. Most samples...

Shown are the seasonal arithmetic means and ranges (minimums–maximums) of n samples grouped along the trophic gradient. Total dissolved phosphorus (TDP), total dissolved nitrogen (TDN), nitrate (NO₃⁻), and ammonium (NH₄⁺) were collected in the field. Dissolved organic Nitrogen (DON) was calculated by difference. Below detection limit is denoted by an asterisk (*); detection limits are 0.03 µmol L⁻¹ for TDP; for 2.50 µmol L⁻¹ TDN; 0.36 µmol L⁻¹ for NO₃⁻; and 0.71 µmol L⁻¹ for NH₄⁺.

FIGURE 2 | Mean daily mixed layer irradiance (E₂₄) across trophic status during the 2017 and 2018 sampling seasons (n = 213). Within the boxplots, the 50th percentile (median) is visualized with a solid horizontal line within each box. The 25th and 75th percentiles are represented by box hinges above and below the median line. On either end of the box, whiskers denote the smallest and largest values within 1.5 × the interquartile range (IQR) and points indicate values beyond 1.5 × the IQR. Dashed lines on the figure represent the light-deficiency thresholds, where values below the lines would be considered light deficient (Table 2).

indicated P-only deficiency (51%) or N and P sufficiency (41%; Figure 6).

Given that indicator values can vary due to influences of phytoplankton community composition and non-algal particulate matter (Hecky et al., 1993), multiple indicator implementation increases assessment strength, especially when observing agreement between ≥2 indicators (Hecky and Kilham, 1988). In 2017, POC:PP and PN:PP ratios were employed as our primary P status indicators with 100% agreement in favor of P-deficiency in oligotrophic reservoirs (Supplementary Table 3). In 2018, P-indicators were expanded to include P debt and P-addition φPSII experiments. All but one oligotrophic sample favored P-deficiency; 2% with complete agreement, and 73% with 3/4 indicator agreement. Overall agreement was much higher for N-indicators than P-indicators with all N-indicators agreeing 63–64% of the time for NH₄⁺ and NO₃⁻ additions. We found 88% of indicator applications favored N-sufficiency for NH₄⁺, while
FIGURE 3 | Patterns of chlorophyll-a (A), light utilization efficiency per unit of chlorophyll-a (B), and gross primary production (GPP\(_{\text{B}}\)) rates normalized to chlorophyll-a (C) across the trophic gradient. Within the boxplots, the 50th percentile (median) is visualized with a solid horizontal line. The 25th and 75th percentiles are represented by box hinges above and below the median line. On either end of the box, whiskers denote the smallest and largest values within 1.5 × the interquartile range (IQR) and points indicate values beyond 1.5 × the IQR. Lowercase letters indicate results from multiple comparison post-hoc tests, where similar letters denote no significant differences between trophic states (Table 5).
FIGURE 4 | Patterns in phosphorus-deficiency across the trophic gradient and 2-year sample period, if applicable, for parameters sampled in 2017 and 2018. 95% of applications favored N-sufficiency for NO$_3^-$ additions (Supplementary Table 3).

**Photosynthesis-Irradiance (P-E) Parameters**

In 2018, $\Phi_{\text{PSII}}$ ranged from 0.33 to 0.66 across the trophic gradient with a mean of 0.48 (Table 4). The $\Phi_{\text{PSII}}$ in all but one sampling event fell below the empirical optimum value of $\sim$0.65, with only 8% of sampling events having values $>0.60$. Land-use had a significant effect on $\Phi_{\text{PSII}}$, where agricultural-pasture had the lowest mean $\Phi_{\text{PSII}}$ and forested was highest. There was no relationship with trophic status. We also found no relationship between trophic status and $\alpha$, although a significant relationship did exist between $\alpha$ and land-use, as well as sampling event (Table 5). Phytoplankton in reservoirs of forested watersheds were the most efficient at utilizing light, whereas those in ag-pasture watersheds were the least efficient. Efficiency was highest in May/June and lowest in August/September. After normalization to chl$_a$, $\alpha^B$ differed across trophic status with phytoplankton of oligotrophic reservoirs being more efficient than those of meso-, eu-, or hyper- trophic reservoirs (Table 5 and Figures 3A, B). As with $\alpha$, $\alpha^B$ demonstrated that efficiency was higher in May/June and in forested watersheds than in August/September or ag-pasture watersheds. Ranging from 92.68 to 491.34 with an average of 292.63 $\mu$mol photons m$^{-2}$ s$^{-1}$ (Table 4), there was no relationship between the light saturation parameter ($E_a$) and trophic status (Table 5). The maximum relative electron transport rate through photosystem II ($r\text{ETR}_{\text{max}}$) ranged from 54.96 to 279.71 with an average of 145.14 (Table 4) and was also not related to trophic status (Table 5). Sampling event was related to both $E_a$ and $r\text{ETR}_{\text{max}}$ wherein both P-E parameters peaked in May/June and reached the lowest values by July/August. Per unit of chl$_a$, however, $E_a^B$ was higher for phytoplankton in oligotrophic reservoirs compared to meso-, eu-, or hyper- trophic reservoirs. $E_a^B$ was also higher in May/June but was not related to land-use (Table 5).

**Gross Primary Productivity**

Ranging from 668 to 701 mmol O$_2$ m$^{-2}$ day$^{-1}$, mean GPP rates were similar between oligo-, meso-, and eu- trophic reservoirs. Hypertrophic reservoirs demonstrated a lower mean GPP of 607 mmol O$_2$ m$^{-2}$ day$^{-1}$. Across individual samples, GPP widely ranged from $\sim$33 to 2,668 (Table 4). There was no relationship between GPP and any chemical or biological parameters nor with trophic status (Table 5).

Rates of GPP normalized to chl$_a$ (GPP$^B$) were negatively related to trophic status, where GPP$^B$ was highest in oligotrophic reservoirs and decreased with increasing eutrophy ($p = 0.001$; Figure 3C). While trophic mean GPP$^B$ rates ranged from $\sim$10 to 430 mmol O$_2$ (mg Chl$a^{-1}$) m day$^{-1}$, the mean GPP$^B$ in oligotrophic reservoirs was $\sim$3, $\sim$7, and $\sim$44 times higher than those in meso-, eu-, and hyper- trophic reservoirs, respectively (Table 4 and Figure 3C). We found positive correlations between GPP$^B$ and physical and P-E parameters, and negative correlations for chemical and biological parameters. Higher GPP$^B$ rates correlated with higher light availability and P-E activity, and lower turbidity, nutrients, and proxies for phytoplankton biomass (Supplementary Table 4).

**DISCUSSION**

Missouri reservoirs have variable light availability, nutrient chemistry, proxies for phytoplankton biomass, and GPP rates across the trophic gradient and between the climatically contrasting summers of 2017 and 2018. P deficiency was the predominant constraint on phytoplankton biomass with rare occurrences of N deficiency. Light deficiency was observed $\sim$25% of the times sampled. Highest in oligotrophic reservoirs, mean GPP$^B$, $E_a^B$, and $\alpha^B$ decreased with increasing eutrophy. Productivity was constrained by light availability, induced through self-shading by phytoplankton communities.

**Production:Biomass Ratios**

The median chl$_a$ concentration in our study reservoirs is 9.3 $\mu$g L$^{-1}$, ranging from 0.9 to 125.7 $\mu$g L$^{-1}$. These concentrations are $\sim$1.5 times higher than the median summer chl$_a$ (6 $\mu$g L$^{-1}$) measured in 2,239 lakes in the Midwest and Northeast United States (Oliver et al., 2017). A global study of 1,316 lakes ranging from tropical to polar, reported a median chl$_a$ concentration of 5.9 $\mu$g L$^{-1}$ (Abell et al., 2012). Within this dataset, the low-temperate lakes had a median chl$_a$ of 13.2 $\mu$g L$^{-1}$ (Abell et al., 2012), 1.4 times higher than our Midwest reservoirs. Neither of these studies, however, differentiated between lakes and reservoirs; reservoirs tend to have higher phytoplankton biomass and productivity (Kimmel and Groeger, 1984).

Just as P is assumed to be the primary constraint on phytoplankton biomass (Schindler, 1974), a similar paradigm exists for lake productivity (Vollenweider, 1976). Global lake observations support the paradigm, showing strong positive relationships between GPP and TP (Hanson et al., 2003; Solomon et al., 2013). While most Missouri reservoirs are consistent with the P-paradigm for biomass accrual, their productivity diverges from the lake-centric model by GPP and GPP$^B$ having, respectively, no relationship and a strongly negative relationship with TP (Supplementary Table 4). The ratio of production to biomass across our trophic gradient is high at low TP (oligotrophic) and low at high TP (hypertrophic). A negative relationship between GPP$^B$ and TP has also been observed in seven Midwestern (Wisconsin) lakes (Lauster et al., 2006). There, GPP$^B$ decreased with increasing eutrophy, wherein the median
FIGURE 5 | Patterns in nitrogen-deficiency across the trophic gradient and 2-year sample period, if applicable, for parameters sampled in 2017 and 2018. Panels show particulate organic carbon to particulate nitrogen (POC:PN) ratios (A), ammonium debts (NH$_4^+$-debt; B), percent change in $\phi_{PSII}$ relative to the control treatment following NH$_4^+$-additions (C), nitrate debts (NO$_3^-$-debt; D), and percent change in $\phi_{PSII}$ relative to the control treatment following NO$_3^-$ additions (E). Dashed horizontal lines indicate nitrogen-deficiency thresholds where applicable. Values above those lines suggest nitrogen-deficiency (Table 2). There were no significant differences between trophic states (Table 5). Within the boxplots, the 50th percentile (median) is visualized with a solid horizontal line. The 25th and 75th percentiles are represented by box hinges above and below the median line. On either end of the box, whiskers denote the smallest and largest values within $1.5 \times$ the interquartile range (IQR) and points indicate values beyond $1.5 \times$ the IQR.
TABLE 7 | A Kruskal Wallis ANOVA was conducted on the 2018 nutrient debts (P debt, NH$_4^+$-N debt, NO$_3^-$-N debt) to test for the effects of sampling event, trophic status, and watershed land-use.

| Factor               | Chi square | p-value | n  | df | Trophic status | Land-use |

| Land-Use             | 4.997      | 0.172   |    |    |                |          |

When factors were significant (bolded, p < 0.05), a Dunn's Test of Multiple Comparisons was conducted, as indicated by the lowercase letters. Different lowercase letters indicate significant differences between factor levels. Letters are ordered alphabetically to indicate trend direction where “a” represents the lowest mean. Heading abbreviations are as follows: O, oligotrophic; M, mesotrophic; E, eutrophic; H, hypertrophic; F, forested; Mix, mixed; Ag-P, pasture; Ag-C, cropland.

FIGURE 6 | Summary of nutrient deficiency across the trophic gradient according to phosphorus (P) and ammonium (NH$_4^+$) debts. Dashed lines indicate deficiency thresholds for P and NH$_4^+$-debts (Table 2). Values above these lines suggest deficiency, thus quadrants 1, 3, and 2 represent N-only deficiency, P-only deficiency, and NP co-deficiency, respectively. Quadrant 4 represents nutrient sufficiency in both P and N.
Phytoplankton Biomass in an Agricultural State

Agriculture is prominent on the Missouri landscape, representing 41% of the land-use, therefore, we would expect P to be in ample supply in these surface waters. Yet, P-deficiency is prevalent. We observe high concentrations of the most bioavailable form of P, DRP, in eu- and hyper-trophic reservoirs within agricultural watersheds. Conservation tillage and surface broadcasting of fertilizer resulted in a 218% increase in concentrations of DRP in Lake Erie (Michalak et al., 2013), and similar practices in Pennsylvania caused DRP to increase 3–28× above background levels following fertilizer application (Kleinman et al., 2009). The prominence of P deficiency in Missouri reservoirs implies that additional inputs of P could result in increased phytoplankton biomass. Thus, implementation of beneficial management practices (BMPs) that would reduce DRP runoff are advised. Climate-induced increases in flow to conclude that self-shading by phytoplankton induced light deficiencies which regulated primary productivity. Increased turbidity via elevated biomass accrual and self-shading were also evidenced by negative correlations of both GPP and α with chl and Kd in a eutrophic lake in the Netherlands (Kromkamp et al., 2008).

Light-deficiency was most common in reservoirs from Missouri watersheds dominated by ag-crop, followed by ag-pasture. While agricultural land use enhances nutrient export to surface waters, row-crop agriculture is often associated with higher nutrient enrichment than low-intensity livestock production (Strayer et al., 2003). Although our high-nutrient systems had more PIM than did our low-nutrient systems, POM concentrations were notably higher than PIM concentrations in nearly all samples. Thus, when light-deficiency occurred, it was induced by self-shading rather than mineral turbidity.

The shallow mixing depths of Missouri reservoirs ensure that phytoplankton communities spend sufficient time in the euphotic zone, reflected in high E24, values and lack of evidence for photoacclimation. As with the GPP methodological issues, Ek derived from fluorometry is often higher than Ek from C-incorporation (Napoléon and Claquin, 2012). Nutrient deficiency, in particular, can perturb the relationship between electron transport rate and C, from which the fluorometric- Ek is derived (Napoléon et al., 2013). The E24:Ek ratio was originally applied using C-incorporation methods (Hecky and Guildford, 1984), therefore, using fluorometrically derived E24:Ek may overestimate the actual degree of light-deficiency. As a physiological measurement, φPSII is often used as a general indicator of phytoplankton stress, with values less than 0.65, as most of our samples were, indicative of light and/or nutrient deficiency (Kromkamp and Forster, 2003), hindering photosynthetic capacity (Kromkamp et al., 2008). Given that the lowest φPSII occurred in the highest-nutrient/lowest-light systems, the physiological stress likely does not reflect a lack of nutrients, but rather, light deficiency. If the phytoplankton were stressed due to nutrient deficiencies, we would have observed significant increases in φPSII post-nutrient additions.

The Role of Nutrients in Constraining Phytoplankton Biomass in an Agricultural State

Agriculture is prominent on the Missouri landscape, representing 41% of the land-use, therefore, we would expect P to be in ample supply in these surface waters. Yet, P-deficiency is prevalent. We observe high concentrations of the most bioavailable form of P, DRP, in eu- and hyper-trophic reservoirs within agricultural watersheds. Conservation tillage and surface broadcasting of fertilizer resulted in a 218% increase in concentrations of DRP in Lake Erie (Michalak et al., 2013), and similar practices in Pennsylvania caused DRP to increase 3–28× above background levels following fertilizer application (Kleinman et al., 2009). The prominence of P deficiency in Missouri reservoirs implies that additional inputs of P could result in increased phytoplankton biomass. Thus, implementation of beneficial management practices (BMPs) that would reduce DRP runoff are advised. Climate-induced increases in flow to
downstream reservoirs need to be countered with increased efforts for nutrient retention on the landscape (Sharpley et al., 2013). These land-based nutrient management efforts, however, may not yield an immediate improvement in water quality. Internal P loading rates are likely high in these reservoirs, as evidenced by high TDP concentrations in the hypolimnions during summer stratification. Extended stratification in a future climate (Woolway and Merchant, 2019) would further exacerbate internal P loading rates (North et al., 2014).

We recommend increased focus on mitigating non-point source P inputs, as it appears that these reservoirs are effective in N removal, resulting in low epilimnetic dissolved inorganic N concentrations, likely due to high rates of denitrification (Gooding and Baulch, 2017). Globally, increasing N-based fertilizer use is resulting in N concentrations in surface waters in excess of phytoplankton demand (Glibert et al., 2016). Despite these trends, studies in Kansas and Arkansas have demonstrated N to be a potentially important constraint on phytoplankton biomass (Dzialowski et al., 2005; Scott and Grantz, 2013). Our mean epilimnetic DON concentrations in reservoirs with row-crop agriculture watersheds were nearly double those in forested watersheds. Globally, urea fertilizer use has increased more than 100-fold in the last four decades (Glibert et al., 2006), and in the United States, nearly 90% of N-based fertilizer being applied is urea instead of ammonium nitrate (Paerl et al., 2016). Urea can exceed 40% of the DON pool (Glibert et al., 2006). Historical urea and DON concentrations are unknown for Missouri reservoirs, but previous publications indicate that 45% of the reservoirs had molar TN:TP ratios < 38 (Jones and Knowlton, 1993), indicating some N deficiency (Guildford and Hecky, 2000).

How Might Light and Nutrients Constrain Phytoplankton Dynamics in a Changing World?

The increase in rainfall intensity associated with climate change, accompanied by the pervasiveness of agriculture and urbanization, will contribute to greater proportions of bioavailable P and N reaching inland waters. Simultaneously, climatically induced stronger and longer-lasting thermal stratification (Woolway and Merchant, 2019) is anticipated to increase hypolimnetic oxygen depletion. Bottom-water anoxia stimulates internal loading, which amplifies hypolimnetic nutrient concentrations (North et al., 2014). Given that ~94% of Missouri reservoirs are already meso-, eu-, or hyper- trophic and quickly develop hypolimnetic anoxia during summer stratification, these Midwestern systems represent potential climate analogs and precursors of the light and nutrient conditions impacting future reservoir phytoplankton dynamics. Although light-deficiency may be alleviated due to shallower mixing depths; most of these characteristically turbid systems will likely still have enough light to support phytoplankton growth, photosynthesis, and nutrient uptake.

CONCLUSION

Under current climatic and anthropogenic influences, both P and light play active roles in controlling phytoplankton biomass and primary productivity in Midwestern reservoirs. Phytoplankton biomass is predominantly constrained by P concentrations during the summer stratified season, despite the abundance of both P and N in the agriculturally dominant region. Although this conclusion aligns with the traditionally accepted P-paradigm for freshwater ecosystems, the demonstration of co-deficiency between light, P, and N should also be acknowledged, especially within the context of the P vs. N and P management debate (Schindler et al., 2008; Paerl et al., 2016). Primary productivity in Midwestern reservoirs contradicts the traditional P-paradigm for lake productivity. GPPB was higher in low-nutrient reservoirs where light was in sufficient supply, and not shaded by high phytoplankton biomass. Here, we offer further evidence for the need to evaluate application of these paradigms to all systems across time and space, especially as we see shifts in climate patterns and anthropogenic activity that will ultimately alter the light and nutrient dynamics of future ecosystems.

The datasets generated for this study are available on request to the corresponding author.

AUTHOR CONTRIBUTIONS

EP designed the study under the direction and leadership of RN who conceived the original idea. EP collected the data by processing water samples, performing the experiments, and conducting laboratory and statistical analyses, performed calculations and modeled parameters described in the manuscript, designed figures, and wrote the manuscript in close consultation with RN. DO coordinated field sampling efforts, contributed data, and assisted in QA/QC of data. All authors contributed to the article and approved the submitted version.

ACKNOWLEDGMENTS

This work was made possible by the Missouri Department of Natural Resources, which generously funds the Missouri Statewide Lake Assessment Program coordinated by the University of Missouri (MU) Limnology Laboratory. We would like to thank the numerous MU Limnology Laboratory employees who contributed to sample collection and analysis. Specifically, thank you to Thomas Swenson, undergraduate research assistant; Carol Pollard and Clare Vanderwerken, laboratory technicians; Cody Kimbell and Matthew Sauer (2017) field rovers; and Madalyn Stoeker and Emily Phaup (2018) field rovers. Thank you to Dr. Greg Silsbe for his insight regarding the “phytotools” R-package, Dr. Christine Spinka for providing statistical consultation, Drs. Chung-ho Lin and Jacob Westhoff for generously sharing environmental chamber space for experiments, Dr. Patrick Neale for providing expert testimonial, and Dr. Alba Argerich for providing helpful comments to improve and clarify the writing of this manuscript. We thank Dr. John R. Jones for his title suggestion. We would also like to
acknowledge Dr. Joy Matthews and the University of California – Davis Stable Isotope Facility for their professional and timely analytical services. Analytical costs were, in part, supported by a Grant-In-Aid of Research from Sigma Xi, the Scientific Research Honor Society.
