Clinical associations of immature breathing in preterm infants: part 1—central apnea

Karen Fairchild1, Mary Mohr2, Alix Paget-Brown1, Christa Tabacaru1, Douglas Lake1, John Delos2, Joseph Randall Moorman3 and John Kattwinkel1

BACKGROUND: Apnea of prematurity (AOP) is nearly universal among very preterm infants, but neither the apnea burden nor its clinical associations have been systematically studied in a large consecutive cohort.

METHODS: We analyzed continuous bedside monitor chest impedance and electrocardiographic waveforms and oxygen saturation data collected on all neonatal intensive care unit (NICU) patients <35 wk gestation from 2009 to 2014 (n = 1,211; >50 infant-years of data). Apneas, with bradycardia and desaturation (ABDs), defined as central apnea ≥10 s associated with both bradycardia <100 bpm and oxygen desaturation <80%, were identified using a validated automated algorithm.

RESULTS: Number and duration of apnea events decreased with increasing gestational age (GA) and postmenstrual age (PMA). ABDs were more frequent in infants <31 wk GA at birth but were not more frequent in those with severe retinopathy of prematurity (ROP), bronchopulmonary dysplasia (BPD), or severe intraventricular hemorrhage (IVH) after accounting for GA. In the day before diagnosis of late-onset septicemia and necrotizing enterocolitis, ABD events were increased in some infants. Many infants continued to experience short ABD events in the week prior to discharge home.

CONCLUSION: Frequency of apnea events is a function of GA and PMA in infants born preterm, and increased apnea is associated with acute but not with chronic pathologic conditions.

Apnea of prematurity (AOP) reflects immaturity of brain-stem and peripheral chemoreceptors and occurs in essentially all infants born at <28 wk gestation and many of those born between 28–34 wk (1–4). AOP is commonly defined as cessation of breathing for >20 s, or >10 s with associated bradycardia or oxygen desaturation (5). In our research, we use the abbreviation ABDn for episodes of central apnea of at least n seconds duration, when accompanied by both bradycardia and desaturation (6). Hypoxia associated with apnea could have detrimental effects on developing tissues and organs resulting in long-term or permanent impairment (6–10), and therapies such as respiratory support and caffeine are only partially successful in reducing the burden of AOP (11,12). Management of refractory apnea, optimum levels and durations of various therapies, and determining readiness for discharge from the neonatal intensive care unit (NICU) continue to be major challenges, and accurate quantitation of apnea is required for both clinical care and outcomes research (13).

Quantitation of apnea in NICU patients has historically involved one of two approaches: medical record documentation of events by bedside caregivers, or short pneumographic recordings of respiratory impedance or inductance signals, heart rate, and oxygen saturation. These approaches are limited, the former by inaccuracy of reporting (14–16) and the latter by requirements for extra attachments to infants and time and expertise required for signal interpretation. As a result, previous studies of AOP are limited by small numbers of infants studied over short periods of time. Our group recently developed a novel automated computer algorithm for quantifying central apnea of prematurity from waveform and vital sign data continuously collected from standard NICU bedside monitors (17). This system was clinically validated and allows identification of central AOP events in large numbers of infants for the entire NICU stay.

Clinical variables affecting the severity of AOP and the timing of resolution as infants approach term-corrected age are not well defined. Prior studies have shown an inverse correlation between gestational age at birth and postmenstrual age at which apnea resolves (18–20). Chronic or acute pathologic processes may also impact the occurrence, severity, and duration of AOP. For example, severe intraventricular hemorrhage (IVH) may be associated with central nervous system dysfunction that could manifest as central apnea (6,21,22), and bronchopulmonary dysplasia, with associated abnormal blood oxygen and carbon dioxide levels, may be associated with dysregulation of peripheral or central chemoreceptor sensitivity and increased apnea. Acute systemic inflammatory processes such as sepsis are known to lead to an abrupt increase in apnea over baseline in some infants (23,24). It is also possible that hypoxemia association with AOP may contribute to pathology such as retinopathy of prematurity (8,10).

or might contribute to neurodevelopmental impairment (7,10,25).

The goals of the current study were twofold: to provide a comprehensive assessment of the burden of central apnea throughout the NICU stay of a large number of preterm infants, and to establish the association of AOP with chronic and acute pathologic processes.

RESULTS

Demographics, Clinical Outcomes, and Respiratory Support

Of 1,372 infants <35 wk gestation admitted to the UVA NICU during the study period, chest impedance waveform and vital sign data were available for analysis for 1,268. Figure 1 shows the type of respiratory support for each infant relative to gestational age (GA) and postmenstrual age (PMA). Fifty-seven of these infants were excluded from the apnea, with bradycardia and desaturation (ABD), analysis because they had no chest impedance data.

Number of ABDs Is Inversely Correlated With GA and PMA

ABD events were assessed when chest impedance, heart rate, and SpO2 data were available and infants were not on mechanical ventilation including nasal intermittent positive pressure ventilation. Median number of days analyzed per infant was 15 (25th-75th percentile 7–34 d, > 50 infant-years of data).

Figure 2a shows an example of an algorithm-detected ABD10 event, with the major features described in the caption. Figure 2b is a histogram showing the number of infants in each GA week with at least one ABD10 event during the NICU stay. Percentage of infants with at least one algorithm-detected ABD based on GA group is as follows: 97% of infants <27 wk, 92% of infants 27–30 wk, 73% of infants 31–32 wk, and 52% of infants 33–34 wk. Note that some infants with no detected ABDs may have been on prolonged mechanical ventilation or may have been transferred to our center at later PMAs for procedures.

Figure 3 includes two heat maps of the average daily number of ABD events for all 1,211 infants based on GA and PMA, with ABD10 and ABD20 shown (3A, 3B). Note that ABD20 events (apnea at least 20 s with associated bradycardia <100 and desaturation <80% of any duration) are a subset of the ABD10 events. In these heat maps, warmer colors denote more apnea events each day, and are most evident in the lower left hand corners—lower GA and PMA. ABD10s persist to later PMAs—for example, the average number of ABD10s at 34 wk PMA is 3 or more, while there is on average <1 ABD20 at 34 wk PMA. The inset of Figure 3a shows that the number of ABD10s at 32–36 wk PMA is about threefold greater for infants <31 wk GA compared to those 31–34 wk. Among the infants <31 wk GA, however, there is no significant impact of GA on the number of ABD10 at these later PMAs.

Table 1. Characteristics and outcomes of 1,211 infants with ABDs analyzed

| GA Group | n | Characteristics | Outcomes |
|----------|---|----------------|----------|
| <27 wk   | 190|                |          |
| <27 wk   | 190|                | 26 <27 wk (n = 25) |
| 27–30 wk | 297|                | 29 27–30 wk (n = 29) |
| 31–34 wk | 724|                | 33 31–34 wk (n = 33) |
| Gestational age (weeks) | | | |
| Birth weight (g) | | | |
| Death before NICU discharge | | | |
| Severe IVH (Grade III-IV) | | | |
| Late-onset sepsis | | | |
| Necrotising enterocolitis | | | |
| Bronchopulmonary dysplasia | | | |
| Treated retinopathy of prematurity | | | |
| Discharged home | | | |
| Postmenstrual age at d/c home | | | |

Data presented as median (25th-75th interquartile) or n (%).

1Denominator is number for whom outcome at 36 wk postmenstrual age is known. 1Laser or bevacizumab.
Figure 2. Apnea, bradycardia, desaturation example, and incidence. Apnea at least 10 s with associated bradycardia <100 beats/min and oxygen desaturation <80% were analyzed using a published algorithm (17). (a) Graphic representation of 60 s of vital sign and waveform data showing a representative ABD event. From top to bottom: Heart rate (HR with 100 beats per minute threshold of bradycardia indicated by the thin green line), oxygen saturation (SpO2 with 80% threshold of desaturation indicated by the thin blue line), chest impedance (CI), filtered chest impedance (FCI), and computer algorithm-detected probability of apnea (P_A). An “ABD10” event is shown, with apnea duration >10 seconds and associated bradycardia and oxygen desaturation. Another shorter breathing pause occurred without associated bradycardia, which did not meet our definition of an “ABD” event. (b) ABDs were analyzed on all infants all times that bedside monitor data were available and the infant was not on mechanical ventilation. Number of infants of each gestational age with at least one algorithm-detected ABD10 event (black fill) and with no events detected (white) is shown.

Figure 3. Mean number of ABD events per day based on gestational and postmenstrual age. For 1,211 infants <35 wk gestational age (GA), ABDs were analyzed during all times that data were available and infants were not on mechanical ventilation. (a) Heat map of mean daily #ABD10s (apnea at least 10 s with associated bradycardia and desaturation) for each week of GA and postmenstrual age (PMA). Color scale goes from blue (zero) to red (eight) events per day. The line graph below shows mean daily #ABD10s for infants <27 wk GA (blue), 27–30 wk (green), and 31–34 wk (red). (b) Mean daily #ABD20s (apnea at least 20 s with bradycardia and desaturation) for each week of GA and PMA.
Lack of Association of Number of ABDs With Severe ROP, BPD, and Severe IVH

Since retinopathy of prematurity (ROP) has been linked to aberrant oxygenation (8,26,27), and since apnea is a major cause of hypoxia (28,29) and rebound hyperoxia (30), we tested the hypothesis that the number of ABD events would be greater in infants who developed severe ROP requiring laser or bevacizumab therapy (Supplementary Figure S1 online). After accounting for GA, we did not find a statistically significant difference in the mean number of ABD10s throughout the NICU stay in 47 infants with treated ROP compared to those without (Supplementary Figure S1a online). We also analyzed ABDs in infants with and without severe IVH (grade III-IV) and in those with BPD, since both of these conditions might be thought to lead to increased frequency of apnea. Considering all ABD10 events throughout the NICU stay, after accounting for GA, there was no significant difference in number of apnea events in the 243 infants with BPD or the 51 infants with severe IVH (Supplementary Figure S1b,c online) compared to infants without these morbidities. We further investigated whether, at later PMA when infants are maturing and nearing NICU discharge, infants with BPD or severe IVH have more central apnea spells with bradycardia and desaturation than those without. At 35 wk PMA, we found that GA is significantly associated with BPD and severe IVH (ROC AUCs 0.927 and 0.817, respectively, P < 0.0001), but that after accounting for GA infants with BPD did not have more ABD10s at 35 wk PMA compared to babies without BPD, (ROC AUC 0.927, change in AUC 0, P = 0.63). For babies with severe IVH, there was a trend toward more ABDs at 35 wk PMA that was not statistically significant (ROC AUC 0.832, change in AUC 0.015, P = 0.085).

Apnea Increases Before Diagnosis of Late-Onset Septicemia and Necrotizing Enterocolitis (NEC)

Acute systemic inflammatory processes can be associated with apnea in preterm infants (23), and we therefore analyzed ABDs in these illnesses (Supplementary Figure S2 online). We identified 28 cases of late-onset sepsis and 21 cases of NEC in infants when they were not on mechanical ventilation and had chest impedance and vital sign data available for analysis >50% of the time in the 48-h period prior to diagnosis. In seven cases of NEC (33%) and 12 cases of late-onset sepsis (43%) infants had at least twofold increased ABD events in the 24-h period prior compared to 24–48 h prior to diagnosis. We also analyzed number of seconds of apnea associated with bradycardia and desaturation in the 24 h period before diagnosis compared to 24–48 h prior, and found similar results as shown in Supplementary Figure S2 online.

ABD Events in the Week Prior to Discharge Home From the NICU

We sought to determine whether infants continued to experience mild, self-resolved or not clinically recognized ABD events in the week prior to NICU discharge. Of the 1,211 infants included in this analysis, 1,048 were discharged home (the others either died or were transferred to another unit). Decisions about readiness for discharge were made by the clinical care team without knowledge of algorithm-detected ABDs. Caffeine was usually discontinued between 32–34 wk PMA, when the infant was off continuous positive airway pressure and no longer having significant clinically detected apnea events requiring stimulation. In our unit during the period of this study, there was a general policy of an 8-d “apnea countdown” with no events requiring intervention before discharge home (18). Minor apnea events that are self-resolved or that occur during feeding generally do not delay discharge, and events that occur following immunizations or general anesthesia near the time of NICU discharge do not restart the apnea countdown. Cardiorespiratory monitors are routinely prescribed for infants going home on supplemental oxygen and are occasionally prescribed for other infants with clinical conditions or events at the discretion of the medical team.

PMA for the 1,048 infants discharged home was 36.6 ± 2.7 wk. In the 7 d prior to discharge, no ABD10s were detected by the automated algorithm in 508 infants (48%), whereas 146 infants (14%) had 10 or more events (Table 2). GA was significantly lower in infants with ABDs in the week before discharge, but PMA at discharge was similar for infants with and without discharge week ABDs. A home apnea monitor or pulse oximeter or both were prescribed at discharge for 168 infants (16%), including all infants discharged on supplemental oxygen and 58 infants discharged on room air. Fourteen infants not on supplemental oxygen and with no ABDs detected by our algorithm in the week prior to discharge were sent home with a monitor, while 103 babies with more than 10 ABDs detected in the week prior to discharge were sent home without a monitor.

### Table 2. ABD10s in the week before discharge home

| No ABDs (n = 508) | 1–10 ABDs (n = 394) | >10 ABDs (n = 146) | P = * |
|------------------|--------------------|-------------------|------|
| Gestational age (weeks) | 33 (31–34) | 31 (28–31) | 30 (27–31) | <0.001 |
| Discharge PMA (weeks) | 36 (35–37) | 36 (35–38) | 36 (35–38) | 0.45 |
| No monitor† at discharge | 460 (91%) | 319 (81%) | 103 (71%) | <0.001 |
| Oxygen and monitor at discharge | 34 (6.7%) | 51 (13%) | 24 (16%) | <0.001 |
| Monitor, no oxygen at discharge | 14 (2.8%) | 24 (6.1%) | 19 (13%) | <0.001 |
| Readmitted for apnea or apparent life-threatening event¶ | 4 (0.8%) | 7 (1.8%) | 4 (2.7%) | 0.71 |

* ≥1 ABD vs. no ABD.
† Apnea monitor or pulse oximeter.
‡ Admitted to UVa Hospital within ≤8 wk of UVa NICU discharge.
§ IVH, intraventricular hemorrhage; NICU, neonatal intensive care unit; PMA, postmenstrual age.
Apparent Life-Threatening Event and sudden infant death syndrome

As shown in Table 2, (15) infants were readmitted within 8 wk of NICU discharge for apnea or apparent life-threatening event, including 2% of infants with one or more discharge week ABDs and 0.8% of infants with no discharge week ABDs ($P = 0.17$).

Reviewing matched birth/death records from the state of Virginia, we found one sudden infant death syndrome death in the study population. The infant was a 32 wk GA twin discharged at 35 wk PMA who died 2 wk after NICU discharge with a forensic autopsy identifying cause of death as sudden infant death syndrome. As we previously reported, during her 3 wk in the NICU, she had excessive periodic breathing—five-fold more than other 32 wk infants—but no clinically recorded apnea and only one computer-detected ABD10 event, which did not occur in the week prior to discharge (31).

DISCUSSION

We provide a quantitative analysis of central apnea throughout the NICU stay of 1,211 preterm infants that confirms some old concepts about AOP and challenges others. We found, as expected, that apnea accompanied by both bradycardia and oxygen desaturation is common in the NICU despite respiratory and pharmacologic treatments administered to nearly all very preterm infants. We confirmed that an acute increase in ABD events may occur in the day prior to diagnosis of an acute illness such as sepsis or NEC. On the other hand, chronic pathologic processes (ROP, BPD, IVH) were not significantly associated with the frequency of central apnea after controlling for gestational age. Finally, we found that longer apneas (ABD20s) resolve earlier than shorter ones, and ABD10 events are not uncommon in the week prior to NICU discharge of healthy preterm infants.

Limitations of the Automated Apnea Detection System

Our apnea detection algorithm requires low or absent variance in the chest impedance signal to detect cessation of breathing efforts, and thus detects only central apnea. Preterm infants also have obstructive apnea, which may or may not be accompanied by some degree of motion of the chest wall and abdomen. The algorithm filters out gross motion artifact before identifying breathing signals in the impedance waveform, but it was not designed to identify obstructive apnea. Prior studies using measures of nasal airflow (thermistors or carbon dioxide detectors) and respiratory inductance plethysmography indicate that the majority of apnea events in preterm infants have both central and obstructive components. Our methodology will miss pure obstructive events but will capture pure central and most mixed central/obstructive events.

We employed a stringent definition of apnea, requiring both bradycardia and oxygen desaturation, in order to measure the most clinically significant events. Many other studies, and the NICHD Consensus Statement (5), define AOP as cessation of breathing with bradycardia or desaturation and give slightly different thresholds for “BD”. Also, the algorithm detects ABD events irrespective of whether they are noticed or are considered clinically important. We previously reported that medical record documentation does not accurately reflect occurrence of ABD events (14), and speculate that many of the algorithm-detected events are self-resolved or are occurring during or following procedures, handling, or feeding and therefore not necessarily documented by bedside caregivers.

Finally, we are reporting only on the number of ABD events, thus we do not make any statements about depth or duration of bradycardia or oxygen desaturation.

Apnea Prior to Diagnosis of Acute Illness

An acute increase in apnea is generally thought to reflect acute stress or illness in preterm infants, and our study provides quantitative evidence of this. Apnea during sepsis or NEC is likely attributable at least in part to release of prostanoids during a systemic inflammatory response (32–34). Many infants did not experience an increase in apnea during sepsis or NEC and we do not have enough cases to determine whether apnea is more likely to occur with specific organisms or reflects a higher severity of illness. Future work will focus on whether real-time analysis and display of abnormal respiratory or other vital sign patterns could provide early warning of potentially catastrophic illnesses, leading to earlier treatment and improved outcomes.

Lack of Association of Apnea Frequency and Chronic Morbidities

After accounting for gestational age, we did not find a greater number of ABD events among infants with severe ROP. Large randomized clinical trials have demonstrated that lowering $SpO_2$ results in lower rates ofROP (27) but a smaller retrospective study suggested that intermittent hypoxia events are linked to more severe ROP (8). It is likely that retinal vascular pathology is related to both hyperoxia and hypoxia and to the phase of development at which aberrant $SpO_2$ occurs. We did not analyze the timing, depth, or duration of hypoxia during apneic events, nor did we assess hypoxia occurring without central apnea (35). Most of our infants with severe ROP were $\leq 25 wk$ GA and were on prolonged mechanical ventilation, which precludes apnea but does not preclude dysoxia that might contribute to ROP.

The finding that infants with BPD did not have more central apnea was surprising, since chemoreceptor dysregulation might be expected in these infants (3). It is possible that infants with significant lung disease are on mechanical ventilation or other respiratory support and caffeine for prolonged periods of time when they are most susceptible, and thus apnea is masked. Infants with BPD may also be more prone to obstructive apnea (28,36,37) which we did not measure. Other studies reviewing apnea or bradycardia events documented in the medical record have reported more events in very preterm infants with BPD (19,20).

We did not find a significant difference in number of ABDs in infants with severe IVH though there was a trend toward slightly more ABDs at later PMA. The number of infants with high-grade IVH in our cohort was small, and we did not separately analyze the even smaller fraction of infants with...
Resolution of Apnea

We found, consistent with other reports (18–20,23), that infants born at gestations <31 wk had apnea to later PMA than those born less preterm. This reaffirms that a specific PMA (e.g., 36 wk) cannot be used as a “safe” benchmark for low apnea risk without also considering GA. In the spectrum from 23–31 wk GA, however, our data show that the number of ABD events by the time infants reached 35 wk PMA was no longer a function of GA at birth. This is in contrast to findings of other studies (19,20) that relied on medical record documentation of events and therefore probably captured more events that required intervention and were considered clinically important. These studies also included bradycardia or apnea episodes and thus likely included obstructive apnea and vagal bradycardia which we did not measure.

Many infants in our cohort who were otherwise ready for discharge home continued to have short algorithm-detected ABDs. These events may have been self-resolved or occurred during feeding or stressors such as immunization (38). Most infants were sent home without a monitor and very few were readmitted to our hospital within 2 mo for apnea or apparent life-threatening event, which is in keeping with other reports (39). Our unit protocol of discharging infants after a week free of needing stimulation to resolve an apneic spell has not changed based on our studies to date, and further work in larger patient populations is needed to establish criteria for safe NICU discharge, since the cost of additional hospital days simply for an “apnea countdown” is substantial (40).

Conclusion

Apnea events with associated bradycardia and oxygen desaturation occur frequently in hospitalized preterm neonates in spite of respiratory support and caffeine. Further research is needed to determine the long-term impact of these events and identify therapies to minimize apnea burden in the NICU.
