ABSTRACT

The outbreak of COVID-19 caused by SARS-CoV-2 urges the development of rapidly and accurately diagnostic methods. Here, one high-sensitivity and point-of-care detection method based on magnetic SERS biosensor composed of Fe3O4-Au nanocomposite and Au nanoneedles array was developed to detect SARS-CoV-2 directly. Among, the magnetic Fe3O4-Au nanocomposite is applied to capture and separate virus from nasal and throat swabs and enhance the Raman signals of SARS-CoV-2. The magnetic SERS biosensor possessed high sensitivity by optimizing the Fe3O4-Au nanocomposite. More significantly, the on-site detection of inactivated SARS-CoV-2 virus was achieved based on the magnetic SERS biosensor with ultra-low limit of detection of 100 copies/mL during 15 mins. Furthermore, the contaminated nasal and throat swabs samples were identified by support vector machine, and the diagnostic accuracy of 100% was obtained. The magnetic SERS biosensor combined with support vector machine provides giant potential as the point-of-care detection tool for SARS-CoV-2.

1. Introduction

The outbreak of coronavirus disease 19 (COVID-19) induced by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has caused worldwide emergency because of its high infection [1,2]. With the implementation of the nucleic acid-based and serological diagnostic tests, such as reverse transcriptase polymerase chain reaction (RT-PCR) and enzyme-linked immunosorbent assay (ELISA), COVID-19 was suppressed by screening and diagnosing the suspected person and then isolating the virus carries [3–5]. However, both the nucleic diagnostic tests and the serological diagnostic tests face some challenges. For example, the present RT-PCR methods are time-consuming and usually costly due to the sophisticated equipment, well-trained personnel, and costly reagents [7–9]. Furthermore, it is worth noting that SARS-CoV-2 will produce the variant virus strains with high transmissibility, which will decrease the accuracy and specificity of the current detection technique [10]. In order to timely detect and control the spreading of SARS-CoV-2, reliable diagnostic methods need to be developed urgently.

Surface Enhanced Raman Scattering (SERS) is a trace detection tool with high sensitivity, fast and simple detection process, which is already applied as biosensors to detect some biomolecules including cancer, virus, and bacteria currently [11–15]. The SERS biosensors possess a simpler and faster detection process compared to the most frequently used RT-PCR. So, the SERS biosensors are of great potential to control the severe epidemic.

However, the biological detection based on SERS faces a huge challenge, that is, the complicated biological environment will interfere and submerge the Raman signals of targets. For solving this problem, a bifunctional composite that combined magnetic beads and SERS-active materials was developed. The magnetic SERS sensors not only could specifically select and detect the targets in a complicated environment by modifying specific protein, but also could enrich objects and further increase the sensibility of SERS. Therefore, the magnetic SERS biosensors have been applied to the detection of biomacromolecules without interferences of physiological environment [16]. Yang Sun et al. developed a sandwich-structure consisting of SERS tags, target influenza...
viruses and highly SERS-active magnetic supporting substrates for the detection of intact and inactivated influenza virus [17]. Tianxi Yang et al. prepared Fe$_3$O$_4$@Au@Ag nanocomposite to detect Adenosine with the limit of detection (LOD) of $10^{-10}$ M. And the SERS protocol achieved the trace detection of Adenosine in urine with an azo coupling which could remove urea in urine [18]. Chongwen Wang et al. developed Fe$_3$O$_4$@Ag SERS system combined with lateral flow immunoassay (LFA) to detect influenza A H1N1 virus and human adenovirus (HAdV) simultaneously [19]. The SERS-based LFA was 2000 times more sensitive than standard colloidal gold strip methods with 50 and 10 pfu/mL LOD for H1N1 and HAdV, respectively. Therefore, Fe$_3$O$_4$@noble metal nanocomposite has a wide application in the biomolecule detection. However, the Fe$_3$O$_4$@noble metal nanocomposite faces the challenge of low sensitivity. In order to increase the SERS enhancement, some mature SERS substrate is applied to combined with Fe$_3$O$_4$@noble metal nanocomposite [17]. Besides, specific recognition and capturing of target molecules plays a vital role in the SERS detection. For the detection of SARS-CoV-2, Angiotensin-converting enzyme 2 (ACE2) was selected because of the nanomolar affinity between ACE2 and SARS-CoV-2 spike protein [20]. And, given the electrostatic interaction between His-ACE2 (short for ACE2 labelled Histidine) and Fe$_3$O$_4$, ACE2 could be immobilized on the surface of Fe$_3$O$_4$ directly. The magnetic orientation of Fe$_3$O$_4$@noble metal nanocomposite and specifically capturing of ACE2 could achieve the select detection of SARS-CoV-2 in complex environment [21, 22].

In this work, we present one high-sensitivity and point-of-care detection method (Scheme 1) for SARS-CoV-2 by developing a Fe$_3$O$_4$-Au nanocomposite modified with ACE2 to capture, enrich, and partially enhance the Raman signals for SARS-CoV-2, and detecting the virus transferred from the Fe$_3$O$_4$-Au-ACE2-virus composite by gold nanoneedles array SERS biosensor [21]. By optimizing the Fe$_3$O$_4$-Au nanocomposite, we obtained the magnetic SERS biosensor with ultrahigh sensitivity. More usefully, on-site detection of inactivated SARS-CoV-2 in the nasal and throat swabs with 100 copies/mL could also be achieved within 15 mins by portable Raman devices, which exhibited excellent point-of-case detection potential. What’s more, support vector machine (SVM) was applied for classifying the contaminated swabs with 100% accuracy. Based on the magnetic SERS biosensor and SVM, the biosensor has the potential to screen and diagnose the SARS-CoV-2 in the current COVID-19 pandemic.

2. Experimental

2.1. materials and instruments

Iron (III) Chloride, Sodium acetate trihydrate, (3-Aminopropyl) trimethoxy silane (APTMS, 97%), Ammonia solution (GR, 25–28%), Gold chloride trihydrate, Sodium citrate dihydrate, sodium hydroxide, Tetraakis (hydroxymethyl) phosphonium chloride solution (THPC, 80% in water), Hydroxylamine solution (50% in water) were from Shanghai Aladdin Biochemical Technology Co., Ltd. Ethylene glycol was purchased from Sinopharm Chemical Reagent Co., Ltd. All the reagents were used directly without purification. SARS-CoV-2 pseudovirus were provided by Sanyou biopharmaceuticals Co., Ltd. The intact and inactivated SARS-CoV-2 viruses were provided by Anhui Provincial Center for Disease Control and Prevention. Heat inactivated process was employed for the inactivation of viruses, and the inactivated details were presented in the supporting information S1 [21,23,24]. The nasal / throat swabs and the disposable virus sampling tube which can maintain the integrity of the SARS-CoV-2 virus were purchased from BIOBASE (BIODUSTRY(SHANDONG) CO., LTD).

The images of Fe$_3$O$_4$ were obtained by scanning electron microscopy (SEM, sigma300). Transmission electron microscopy (Ta100X200 G2) was used to characterize the morphology and element mapping of Fe$_3$O$_4$@Au nanocomposite with an accelerating voltage of 200 kV. X-ray photoelectron spectroscopy (XPS, from Thermo Fisher Scientific) was employed to assess the chemical properties of Fe$_3$O$_4$@Au nanocomposite. The UV-Vis images were obtained by a PerkinElmer Ultraviolet visible spectrophotometer (Lambda 950). For the Raman spectra of Rhodamine 6 G (R6G) and pseudovirus in the lab, Renishaw inVia Reflex laser confocal micro-Raman spectrometer was used to acquire the Raman signals. And for the on-site detection of inactivated virus, the portable Raman spectrometer (from Shanghai Oceanhood opto-electronics Co., Ltd) was applied.

2.2. Preparation of Fe$_3$O$_4$-Au nanocomposite

Monodisperse Fe$_3$O$_4$ microspheres were synthesized according to a modified method proposed by Hong Deng [25]. The mixture of 0.6 g FeCl$_3$, 3 g CH$_3$COONa and 30 mL ethylene glycol was heated to 60 °C and stirred vigorously for 1 h, then the transparent solution was obtained. The prepared solution was poured into Teflon-lined stainless-steel autoclave and heated at 190 °C for 6 h. The black product was collected by the external magnetic field, cleaned with ethanol and deionized water (DI water) two times separately, and dried at 60 °C for 12 h.
The Au nanoparticles were loaded on Fe$_3$O$_4$ microspheres by the modified method proposed by Zihao Li et al. [26,27]. The synthesis process of Fe$_3$O$_4$-Au was divided into three parts: functionalizing the Fe$_3$O$_4$ with the amino functional group, preparing the above 2 nm Au seeds and adsorbing of Au seeds, and growing the Au seeds [19,28,29].

Firstly, add 2 mL ammonia and 1 mL APTMs to the mixture of 40 mg Fe$_3$O$_4$, 40 mL DI water of and 80 mL absolute ethyl alcohol, and stir for 12 h mechanically. The product was collected by magnet, and cleaned by ethanol and deionized water. The next part was the synthesis of Au seeds, 1 mL THPC solution (12 μL THPC in 1 mL DI water) and 0.5 mL NaOH solution (1 M) were added into 45 mL DI water. The solution was stirred violently for 5 mins, and added 2 mL HAuCl$_4$ (27 mM) quickly. The prepared solution was stirred for 2 h at room temperature. Pour the solution contained Au seeds into the prepared Fe$_3$O$_4$-NH$_2$ and stir for 12 h. Then clean the Fe$_3$O$_4$-Au seeds with water. The ultimate step is the growth of Au seeds. Add 3 mL sodium citrate (1 wt%) and 1.5 mL HAuCl$_4$ (27 mM) to 50 mL Fe$_3$O$_4$-Au seeds solution. Then add 6 μL hydroxylamine (60 wt%) in above solution and stir for 6 h. Finally, collect the product by magnet and clean with DI water. The sizes ratio between Fe$_3$O$_4$ microspheres and Au nanoparticles is regulated to optimize the SERS performance by changing the stepwise growth times of Au nanoparticles from two to six times. The ultimate nanocomposites were dispersed in 50 mL DI water to be used.

2.3. Modification Fe$_3$O$_4$-Au with His-ACE2

Before detecting of SARS-CoV-2 pseudovirus and inactivated virus, the SERS-active substrate Fe$_3$O$_4$-Au nanocomposite should be modified with the specific protein to capture targets. Human His-ACE2 (0.35 mg/mL) was mixed with Fe$_3$O$_4$-Au nanocomposite and incubated for 2 h. After the combination between Fe$_3$O$_4$-Au nanocomposite and His-ACE2, it is necessary to wash the above product to remove the redundant ACE2.

2.4. SERS detection for pseudovirus and inactivated virus of SARS-CoV-2

For the detection of pseudovirus in the laboratory, 20 μL $2.76 \times 10^5$ copies/mL virus was diluted to the concentration gradient from $2.76 \times 10^4$ to $2.76 \times 10^2$ copies/mL, and mixed with 25 μL Fe$_3$O$_4$-Au-ACE2 thoroughly. Then acquire the Raman signals by the Confocal Raman Spectrometer with 785 nm near-IR laser source with the following parameters: 1 s acquisition time and 0.6 mW laser power.

For SARS-CoV-2 on-site test, taking inactivated virus detection in nasal swabs solution as an example. Firstly, mix 100 μL negative and positive nasal / throat swabs (1300 copies/mL to 60 copies/mL) with Fe$_3$O$_4$-Au-ACE2 thoroughly, then enrich the composite with external magnet and wash it by several times. The composite was deposited on Au nanoneedles array and dried (the preparation process of Au nanoneedles array was depicted in Supporting Information S2). Then detection was measured by portable Raman spectrometer (RMS 1000) with the following parameters: 785 nm laser source, 2 s acquisition time, and 100 mW laser power.

2.5. Support vector machine and date analysis

SVM models were trained using toolbox LIBSVM 3.24 for MATLAB [30]. The training accuracy of Linear kernels, Polynomial kernel and RBF kernel were verified through the cross-validation program, and finally the Linear kernel with the highest accuracy was selected. In our study, a total of 603 Raman shifts from 500 to 1800 cm$^{-1}$ were chosen as the variables for SVM using MATLAB. The date matrix consisted of 200
3. Results and discussion

3.1. Characterization of Fe₃O₄-Au nanocomposite

We prepared the Fe₃O₄-Au nanocomposite which Au nanoparticles (Au NPs) were loaded on the surface of Fe₃O₄ microspheres. Fig. 1 showed the morphology and properties of Fe₃O₄ and Fe₃O₄-Au nanocomposite. Fe₃O₄ microspheres were spherical and their sizes were about 150 nm with excellent monodisperse (Fig. 1(a)). In terms of the microstructure of Fe₃O₄ microsphere, it was constituted with many ultrafine Fe₃O₄ nanoparticles. As depicted in Fig. 1(b), the Au nanoparticles (above 20 nm) were loaded on the surface of Fe₃O₄ microspheres successfully. The insert in Fig. 1(b) was the HRTEM image of Fe₃O₄-Au nanocomposite. The crystal fringes with a spacing of 0.25 nm were ascribed to the (311) crystal plane of Fe₃O₄ microspheres. The twins in Au crystal can be observed, which were ascribed to the (111) and (200) crystal planes. The formation of Fe₃O₄-Au nanocomposite was attributed to the electrostatic interaction between positively charged amino functional groups and negatively charged colloidal Au.

Some convincing evidence could also prove the successful load of Au NPs on the Fe₃O₄ microspheres. Fig. 1(c) was the corresponding elemental mapping images, which exhibited the relative location between Au NPs and Fe₃O₄ microspheres. Fig. 1(d) showed the analysis of Fe 2p for Fe₃O₄-Au nanocomposite. The peaks located at 724.78 eV, 713.08 eV, and 710.68 eV were attributed to 2p₁/₂ and 2p₃/₂ respectively. And the appearance of the peak located at 718.08 eV indicated the formation of γ-Fe₂O₃, which was due to partial oxidation of Fe₃O₄. As shown in Fig. 1(e), the UV-Vis spectra of Fe₃O₄ and Fe₃O₄-Au nanocomposite showed the typical 521 nm absorption peak that was corresponding to the plasma resonance of Au NPs. XRD analysis can also prove the successful preparation of Fe₃O₄-Au nanocomposite (Fig. S1(a) and (b) were the XPS spectrum for Fe₃O₄-Au nanocomposite with magnetic enrichment (red line) and without magnetic enrichment (black line). (c) The schematic diagram of magnetic SERS biosensor structure which is Fe₃O₄-Au nanocomposite combined with Au nanoneedles array. (d) The Raman mapping image of 10⁻⁶ R6G based on Fe₃O₄ microspheres combined with Au nanoneedles array (red lines) and Fe₃O₄-Au nanocomposites combined with Au nanoneedles array (blue lines).
of Au (JCPDS, card No.19–0629). We suggested that the Fe₃O₄-Au nanocomposite was prepared successfully.

As shown in Fig. 1 (f), the magnetism of Fe₃O₄ microspheres and Fe₃O₄-Au nanocomposite were characterized by the magnetic hysteresis loop. The magnetic saturation (MS) values of Fe₃O₄ and Fe₃O₄-Au nanocomposite were around 47.83 emu/g and 45.567 emu/g, respectively. The reduction of MS values was tiny, proving that the magnetic property was still excellent after loading Au NPs. And the hysteresis loop wasn’t detected, indicating that Fe₃O₄-Au nanocomposite was super-paramagnetic at room temperature. The magnetic property of Fe₃O₄-Au was favorable to separate the target substance from the complex environment. In conclusion, the above experimental results indicated the successful preparation of the Fe₃O₄-Au nanocomposite.

3.2. The SERS performance of Fe₃O₄-Au nanocomposite and magnetic SERS biosensor

In a typical SERS analysis, the enhancement factor (EF) and limit of detection (LOD) are used to evaluate the SERS performance. R6G aqueous solution of different concentrations (from 10⁻⁶ M to 10⁻⁸ M) was selected to characterize the SERS performance. The resonance absorption peak of R6G is located at 524 nm. So, the Raman signals are collected with 532 nm laser source for producing resonance enhancement effect [34]. As shown in Fig. 2(a), the characteristic band around 611 cm⁻¹ was corresponding to the C-C-C ring in-plane. The bands at 771 and 1184 cm⁻¹ were attributed to the symmetric modes of in-plane C-C stretching and C-O-C stretching vibrations [35]. The nanocomposite possessed excellent sensitivity with the LOD of 10⁻⁸.
M, and EF was \(1.4 \times 10^8\) for \(10^{-6}\) M R6G with the irradiation laser of 532 nm according to the equation of SERS enhancement factor: \(\text{EF} = \frac{I_{\text{SERS/Au}}} {I_{\text{Raman/NaRaman}}}\) (the detail of calculation is described in the Supporting Information S3) [36,37]. We assessed the magnetic enrichment capacity of Fe\(_3\)O\(_4\)-Au nanocomposite by comparing the direct SERS detection and SERS enrichment-detection. Direct SERS detection referred that the Fe\(_3\)O\(_4\)-Au nanocomposite was deposited and dried on silica glass, and then R6G were deposited on the Fe\(_3\)O\(_4\)-Au nanocomposite. SERS enrichment-detection referred that the mixture of Fe\(_3\)O\(_4\)-Au nanocomposite and R6G was enriched by external magnet, and deposited on silica glass for SERS detection [38]. The SERS enrichment-detection of \(10^{-6}\) M R6G with the magnetic field is around four times better than those without magnetic field as shown in Fig. 2(b). The enrichment effect with the external magnet was in favor of enhancing SERS performance for Fe\(_3\)O\(_4\)-Au nanocomposite.

In order to increase the optical enhancement performance of Fe\(_3\)O\(_4\)-Au nanocomposite, the nanocomposite captured target molecules was deposited on Au nanoneedles array for detection. The more details of Au nanoneedles array (GNA) can refer to our published literature [21,39]. The nanoneedles with a 15 nm apex diameter are arranged with an oblique angle of 45° to Si substrates. The “lighting-rod” effect induced by sharp tips and electromagnetic field coupling caused by the special nanostructure GNA synergistically enhance the SERS effect with the EF of \(10^5\) for R6G. The magnetic SERS biosensor was constituted with two parts: Fe\(_3\)O\(_4\)-Au nanocomposite and Au needles array as depicted in Fig. 2(c). The SERS enhancement of Fe\(_3\)O\(_4\) combined with GNA and Fe\(_3\)O\(_4\)-Au nanocomposite combined with GNA were compared in Fig. 2(d). The results indicated that Au NPs on the surface of Fe\(_3\)O\(_4\) microspheres played a significant role in the SERS enhancement. Therefore, we concluded that the enhancement mechanism for our magnetic SERS biosensor was ascribed to local surface plasmon resonance produced by Au nanoparticles coupling Au nanoneedles array.

### 3.3. Optimization of Fe\(_3\)O\(_4\)-Au nanocomposite for immobilizing ACE2 and ultra-sensitive detection of SARS-CoV-2 pseudovirus

We prepared the Fe\(_3\)O\(_4\)-Au nanocomposite with different size ratios between Fe\(_3\)O\(_4\) microspheres and Au NPs by adjusting the stepwise growth times of Au NPs. The in-situ stepwise growth of Au NPs on the Fe\(_3\)O\(_4\) microspheres was achieved by the iterative reduction process from 2 times to 6 times with NH\(_4\)OH [40]. As shown in Fig. 3(a), along with the increasing stepwise growth times of Au NPs, the size of Au NPs would increase and the load density of Au NPs would decrease. The target of optimization was to obtain the nanocomposite which could immobilize ACE2 as many as possible. ACE2 played a significant role in SARS-CoV-2 detection with our magnetic SERS biosensor, a series of fluorescence tests were implemented to prove the importance of ACE2. Polypeptide labelled 5-FITC (LVMLGLNVQLRYSK(5-FITC), denoted as FITC) could recognize SARS-CoV-2 spike protein specifically, which was applied to combined with pseudovirus and provide fluorescence signals [41]. The fluorescence intensity of Fe\(_3\)O\(_4\)-Au-ACE2-pseudovirus-FITC composite is higher than the other control groups (Fe\(_3\)O\(_4\)-Au-pseudovirus-FITC composite, Fe\(_3\)O\(_4\)-Au-ACE2-FITC composite, Fe\(_3\)O\(_4\)-Au-FITC composite) as shown in Fig. 3(b). We suggested that more ACE2 on the surface of Fe\(_3\)O\(_4\)-Au nanocomposite was beneficial to detect SARS-CoV-2.

Fig. 3(c) was the SERS spectra of ACE2 (0.35 mg/mL) assembled onto magnetic SERS biosensor with different stepwise growth times of Au NPs. Along with the increasing of times, more peaks appeared and the intensity of the Raman band at \(1324\) cm\(^{-1}\) was stronger. The Fe\(_3\)O\(_4\)-Au nanocomposite with 5 times or 6 times growth presented the most optimal performance and the strongest Raman signal intensity. In our work, ACE2 served as a “hunter” was applied to capture the target virus due to the affinity between ACE2 and SARS-CoV-2 spike protein [20]. More ACE2 molecules would capture more target molecules and be in favor of the virus detection. Therefore, we preferred to develop the magnetic Fe\(_3\)O\(_4\)-Au nanocomposite that could graft more ACE2 and exhibit outstanding enhanced optical performance. The Raman intensity was proportional to the quantity of analyte normally, so the Fe\(_3\)O\(_4\)-Au nanocomposite of 5 times or 6 times stepwise growth was the best magnetic SERS substrate for SERS detection. However, compared to the Au NPs grown 5 times, 6 times growth would cause severe agglomeration and be more time-consuming. Considering cost-effectiveness, we chose the Fe\(_3\)O\(_4\)-Au nanocomposite with 5 times stepwise growth to be used.

The difference in SERS performance caused our interest to explore the mechanism for the above different SERS enhancement of ACE2. We attributed the phenomenon to two reasons which were the load density and size of Au NPs [42]. The combination between His-ACE2 and Fe\(_3\)O\(_4\)-Au nanocomposite is attributed to the electrostatic attraction between Fe\(_3\)O\(_4\) microspheres and Histidine, so load density of Au NPs is essential to the attachment of ACE2. The load density of Au NPs should maintain an appropriate value which is beneficial for combining ACE2 molecules and enhancing SERS signals. Along with the increasing growth times of Au NPs, the load density of Au NPs was gradually decreasing, and the exposed area of Fe\(_3\)O\(_4\) was gradually increasing as shown in Fig. 3(a). Correspondingly, the SERS performance was better along the increasing area of Fe\(_3\)O\(_4\) microsphere as shown in Fig. 3(c). The size of Au NPs also had greatly influenced the SERS performance of magnetic SERS biosensor. Along with increasing the reduction time, the size of Au NPs was bigger. The increasing size of Au NPs would cause red-shift of surface plasmon resonance, which was more close to excitation wavelength (785 nm) [40]. The increase of size tended to produce stronger electromagnetic enhancement and obtained more excellent SERS performance.

After optimizing the Fe\(_3\)O\(_4\)-Au nanocomposite, the nanocomposite combined Au nanoneedles array was applied to detect SARS-CoV-2. Before on-site detection for our magnetic SERS biosensor, the sensitivity for SARS-CoV-2 detection was necessary to be accessed. Therefore, its pseudovirus model was detected directly with the magnetic SERS biosensor in the lab by the confocal micro-Raman spectrometer at 785 nm laser source, the process was shown schematically in Fig. 3(d). The Raman spectra of pseudovirus with different viral loads (2.76 \(\times\) \(10^4\), 2.76 \(\times\) \(10^5\) copies/mL) were illustrated in Fig. 3(e), the solid line was the Raman signal acquired by the confocal micro-Raman spectrometer and the dashed line was fitted Raman peaks by PeakFit software. The Raman shift would change slightly and the Raman peak would broaden for the spectra of SARS-CoV-2 pseudovirus because of the orientation of molecule absorption for macromolecules [43]. Hence, we deconvoluted the peaks into individual components and acquired a more accurate analysis of the virus with PeakFit software [44].

The magnetic SERS biosensor possessed ultrahigh sensitivity for SARS-CoV-2 pseudovirus, with the LOD of 276 copies/mL. We could observe five characteristic peaks at 545 cm\(^{-1}\), 1000 cm\(^{-1}\), 1284 cm\(^{-1}\), 1310 cm\(^{-1}\), 1445 cm\(^{-1}\). The band around 545 cm\(^{-1}\) assigns to S-S stretching [45,46]. The peak located at 1000 cm\(^{-1}\) is attributed to Phenylalanine ring mode, the Raman shift around 1284 cm\(^{-1}\) is primarily related to Amide III (\(\alpha\)-helix structure) [44,47]. Raman shift around 1445 cm\(^{-1}\) is responsible for the stretching vibration mode of Amino acid [48]. The magnetic SERS biosensor with ultrahigh sensitivity for detecting pseudovirus could further be applied for the on-site detection of SARS-CoV-2 in nasal and throat swabs.

### 3.4. Identification of SARS-CoV-2 from nasal and throat swabs

On-site screening of SARS-CoV-2 is an essential capability for the SERS-based diagnostic tools. The magnetic SERS biosensor can separate the target analyte from the complicated liquid environment by external magnetic field directly and simplify the detection process. Compared to the label-SERS biosensor, the direct label-free SERS biosensor is the
simplest way to detect targets [49]. For estimating the specificity and accuracy of the magnetic SERS biosensor, the direct detection of the SARS-CoV-2 virus was performed by as-prepared Fe$_3$O$_4$-Au-ACE2 nanocomposite combined with GNA. To ensure the security for experimenters, we manipulated the detection process with simulated samples, which mixed inactivated SARS-CoV-2 virus and nasal and throat swabs of a healthy experimenter.

Fig. 4 (a) and (b) were the Raman spectra of simulated nasal and throat swabs with different viral loads from 1300 copies/mL to 100 copies/mL. (c) The mapping of Raman spectra for simulated nasal swabs with 60 copies/mL viral loads. (d) The mapping of Raman spectra for simulated nasal swabs (100 copies/mL, blue lines) and negative throat swabs (red lines). (e) The predicted model by SVM linear kernel function for simulated throat and nasal swab (100 copies/mL). Value 1 is a prediction as positive swabs solution and value 2 is a prediction as negative swabs solution.

From the perspective of Raman spectra, the characteristic Raman shifts of simulated positive and negative nasal / throat swabs (with 100 copies/mL) were similar as shown in Fig. 4(d) and Fig. S3(b). The obvious distinction was the Raman intensity, that is, the Raman intensity of simulated positive nasal and throat swabs was higher than those of negative samples. We concluded that the difference of Raman intensity was attributed to the ACE2 structure deformation. The N- and C-terminal domains would move closer after binding SARS-CoV-2 spike protein, the deformation might cause ACE2 closer to the SERS-active site and increase the SERS intensity [50]. However, we can’t discriminate the samples with virus rapidly only according to the difference of intensity sometimes. Therefore, in order to deal with the high similarity of Raman spectra between ACE2 and SARS-CoV-2 virus, SVM was applied to establish classification model which aimed to classify the positive

suitable for detecting SARS-CoV-2 virus with 100 copies/mL and over viral loads. The whole detection process only took 15 min. Thus, the biosensor with high sensitivity and short detection time is practical for on-site detection of SARS-CoV-2 virus.
samples from unknown samples. And PAC was applied to discover the characteristics of Raman spectra of simulated nasal / throat swabs. As shown in Fig. S4, PCA loading plots were performed by with the eigenvectors of covariance matrix and the Raman spectra was projected onto the PCA score space. The measured SERS spectra were classified by SVM classification models with linear function, polynomial function, and Gaussian radial basis function (RBF) [31]. As shown in Fig. S5, the parameters were optimized by cross validation of training set data. The maximum diagnostic accuracy with 100%, 98.3%, and 55% were obtained for linear kernel function, polynomial kernel function, and RBF, respectively. According to the result of cross validation, we selected the linear kernel function as the algorithm model to establish classification model.

The date matrix consisted of 200 Raman spectra by 604 variables, including 100 simulated nasal swabs and 100 simulated throat swabs, respectively. The Raman shifts from 500 to 1800 cm\(^{-1}\) were defined as the region of interest (ROI), because reliable identification of protein located at this spectral region [44]. The spectra of simulated nasal swabs were randomly organized and divided into two groups: training sets and test sets, composed of 60 and 40 samples, respectively. Among, training sets consisted of 25 positive samples and 35 negative samples. For simulated throat swabs, 30 positive samples and 30 negative samples were trained to predict 40 unknown samples. Fig. 4(e) illustrated the classification results of the throat and nasal swabs, the star pattern and circle pattern with two colors represented the positive and negative nasal/throat samples, respectively. The SVM algorithm could distinguish the different samples successfully without misclassification. The confusion matrix for the training set and test set for throat / nasal swabs was listed in Table 1. The model possessed excellent outcomes with 100% accuracy both for two types of simulated samples. SERS spectra of contaminated viral samples can be identified based on SVM model rapidly, and the magnetic SERS biosensor combined with the SVM possesses the universality for two kinds of samples (throat swabs and nasal swabs). The rapid and ultra-sensitive magnetic SERS biosensor possessed high potential in the on-site detection of SARS-CoV-2.

### 4. Conclusion

We have developed one high-sensitivity and point-of-care detection method for SARS-CoV-2 based on Fe\(_3\)O\(_4\)-Au nanocomposite and Au nanoneedles array SERS biosensors. Fe\(_3\)O\(_4\)-Au nanocomposite was employed to capture and enrich virus, which was partially responsible for enhancing the Raman signals for SARS-CoV-2. By adjusting the growth times of Au NPs on the surface of Fe\(_3\)O\(_4\)-Au nanocomposite, the most optimal magnetic SERS biosensor with high sensitivity was obtained. More importantly, this method based on magnetic SERS biosensor could detect the contaminated viral samples with 100 copies/\(\mu\)L during 15 mins by portable Raman spectrometer. SVM was employed to classify the positive samples with the accuracy of 100%. With excellent sensitivity and accuracy, the magnetic SERS biosensor has great potential to restrain the COVID-19 epidemic.
