Abstract: A search for supersymmetry is presented based on proton-proton collision events containing identified hadronically decaying top quarks, no leptons, and an imbalance pmissT in transverse momentum. The data were collected with the CMS detector at the CERN LHC at a center-of-mass energy of 13 TeV, and correspond to an integrated luminosity of 35.9 fb−1. Search regions are defined in terms of the multiplicity of bottom quark jet and top quark candidates, the pmissT, the scalar sum of jet transverse momenta, and the mT2 mass variable. No statistically significant excess of events is observed relative to the expectation from the standard model. Lower limits on the masses of supersymmetric particles are determined at 95% confidence level in the context of simplified models with top quark production. For a model with direct top squark pair production followed by the decay of each top squark to a top quark and a neutralino, top squark masses up to 1020 GeV and neutralino masses up to 430 GeV are excluded. For a model with pair production of gluinos followed by the decay of each gluino to a top quark-antiquark pair and a neutralino, gluino masses up to 2040 GeV and neutralino masses up to 1150 GeV are excluded. These limits extend previous results.

I. INTRODUCTION

The observation [1–3] of a Higgs boson ($H$) has been the most significant discovery to date at the CERN LHC. However, its relatively small mass of about 125 GeV [4] can be understood in the context of the standard model (SM) only through fine tuning of the associated quantum loop corrections [5]. A compelling model that can account for the observed Higgs boson mass without this fine tuning is the extension to the SM called supersymmetry (SUSY) [6–14].

The main assertion of SUSY is the existence of one or more particles, called superpartners, for every SM particle, where the spin of a superpartner differs from that of its SM counterpart by a half integer. The superpartners of quarks, gluons, and Higgs bosons are squarks $\tilde{q}$, gluinos $\tilde{g}$, and Higgsinos $\tilde{\chi}_0$, respectively, while neutralinos $\tilde{\chi}_0^0$ and charginos $\tilde{\chi}_\pm^0$ are mixtures of the superpartners of electroweak and Higgs bosons. In so-called natural models of SUSY [15], the top squark, bottom squark, gluino, and Higgsinos are required to have masses no larger, and often much smaller, than a few TeV, motivating searches for these particles at the LHC.

In this paper we present a search for top squarks and gluinos. The data were collected in 2016 by the CMS experiment at the LHC and correspond to an integrated luminosity of 35.9 fb$^{-1}$ of proton-proton ($pp$) collisions at a center-of-mass energy of 13 TeV. The search is performed in all-hadronic events with a large imbalance $p_T^{\text{miss}}$ in transverse momentum, where by “all-hadronic” we mean that the final states are composed solely of hadronic jets. Recent searches for SUSY in a similar final state are presented in Refs. [16–20]. The current analysis is distinguished by the requirement that identified (“tagged”) hadronically decaying top quarks be present. It represents an extension, using improved analysis techniques and a data sample 16 times larger, of the study in Ref. [20].

In the search, top squarks are assumed to be produced either through the direct production of a top squark-antisquark pair or in the decay of pair-produced gluinos. They are assumed to decay to the lightest neutralino $\tilde{\chi}_1^0$—taken to be a stable, weakly interacting, lightest SUSY particle (LSP)—and a quark. Since the LSP interacts only weakly, it does not produce a signal in the detector, thus generating $p_T^{\text{miss}}$. A novel top quark tagging algorithm is employed to identify hadronically decaying top quarks produced in the decay chains. The algorithm makes use of the facts that a top quark essentially always decays to a bottom quark and a W boson, and that—in hadronic decays—the W boson decays to a quark-antiquark ($q\bar{q}'$) pair. The algorithm recognizes three different types of decay topology for the top quark. In order of increasing Lorentz boost for the top quark, these are: (i) three distinct jets with no more than one of them identified as a bottom quark jet (“$b$ jet”), where two non-$b$ jets arise from the $q$-
and $q'$ produced in the $W$ boson decay; (ii) two distinct jets, one of which corresponds to the $b$ quark and the other to the merged $qq'$ decay products from the $W$ boson; and (iii) a single jet representing the merged decay products of the $b$ quark and $W$ boson. By accounting for these three different topologies, the algorithm achieves high detection efficiency over a wide range of top quark transverse momentum $p_T$.

Events are selected that contain large $p_T^{miss}$, at least four jets, at least one identified $b$ jet, at least one identified top quark, and no identified leptons. Search regions are defined based on the number $N_b$ of identified $b$ jets, the number $N_T$ of top quark candidates, the $p_T^{miss}$, the scalar sum $H_T$ of the $p_T$ of jets, and the $m_{T2}$ mass variable, where $m_{T2}$ is calculated using the reconstructed top quarks.

The largest source of SM background arises from top quark-antiquark pair ($t\bar{t}$), single top quark, and $W$ + jets production, namely from events in which a leptonically decaying $W$ boson yields both a high-momentum neutrino, generating $p_T^{miss}$, and a charged lepton that is either not identified, not reconstructed, or outside the analysis acceptance. Another important source of background is $Z + jets$ production followed by $Z \rightarrow \nu \bar{\nu}$ decay. Quantum chromodynamics (QCD) multijet events, namely events with multijet final states produced exclusively through the strong interaction, can contribute to the background if mismeasurement of jet $p_T$ yields large reconstructed $p_T^{miss}$ or if a semileptonically decaying charm or bottom hadron is produced. Events with $t\bar{t}$ production in which both top quarks decay hadronically are indistinguishable from QCD multijet events and are included in the QCD multijet background. Because of the relatively small $t\bar{t}$ cross section, these $t\bar{t}$ events constitute only a few percent of the evaluated QCD multijet background. Small sources of background include multiple vector boson production and events with a $t\bar{t}$ pair produced in association with a $Z$ boson.

**II. SIGNAL MODELS**

Signal scenarios for SUSY are considered in the context of simplified models [23–27]. For direct top squark pair production, the simplified model denoted “T2tt” is examined. In this model, each top squark $\tilde{t}$ decays to a top quark and the LSP: $\tilde{t} \rightarrow t\tilde{\chi}_1^0$. For top squark production through gluino decay, the models described in the following two paragraphs are considered.

In the model denoted “T1ttt,” pair-produced gluinos each decay to an off-shell top squark and an on-shell top quark. The off-shell top squark decays to a top quark and the LSP. The gluino decay is thus $\tilde{g} \rightarrow t\tilde{\chi}_1^0$. The T1ttt model provides sensitivity to situations in which the top squark is too heavy to be produced directly while the gluino is not. In the “T1ttbb” model, pair-produced gluinos each decay via an off-shell top or bottom squark as $\tilde{g} \rightarrow t\tilde{\chi}_1^0$ (25%), $\tilde{g} \rightarrow b\tilde{\chi}_1^+$ or its charge conjugate (50%), or $\tilde{g} \rightarrow b\tilde{\chi}_1^0$ (25%), where $\tilde{\chi}_1^+$ is the lightest chargino. The mass difference between the $\tilde{\chi}_1^+$ and the LSP is taken to be $\Delta m(\tilde{\chi}_1^+,\tilde{\chi}_1^0) = 5$ GeV. Thus the $\tilde{\chi}_1^+$ is taken to be nearly mass degenerate with the $\tilde{\chi}_1^0$, representing the expected situation should the two particles appear within the same SU(2) multiplet [25]. The $\tilde{\chi}_1^+$ subsequently decays to the LSP and an off-shell $W$ boson. The T1ttbb model provides sensitivity to mixed states of top and bottom squarks.

In the model denoted “T5tttt,” the mass difference between the top squark and the LSP is $\Delta m(\tilde{t},\tilde{\chi}_1^0) = 175$ GeV. Pair-produced gluinos each decay to a top quark and an on-shell top squark. The top squark decays to a top quark and the LSP. This model provides sensitivity to mixed states of top and bottom squarks. In the model denoted “T5ttcc” the mass difference between the top squark and the LSP is $\Delta m(\tilde{t},\tilde{\chi}_1^0) = 20$ GeV and the top squark decays to a charm quark and the LSP. Small sources of background include multiple vector boson production and events with a $t\bar{t}$ pair produced in association with a $Z$ boson.

III. THE CMS DETECTOR

The CMS detector is built around a superconducting solenoid of 6\(m\) internal diameter, which provides a magnetic field of 3.8 T. Within the solenoid volume are a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter (ECAL), and a brass and scintillator hadron calorimeter (HCAL). The tracking detectors extend over the pseudorapidity range \(|\eta| < 2.5\). The ECAL and HCAL, each composed of a barrel and two endcap sections, cover \(|\eta| < 3.0\). Forward calorimeters on each side of the interaction point encompass \(3.0 < |\eta| < 5.2\). Muons are detected within \(|\eta| < 2.4\) by gas-ionization chambers embedded in a steel magnetic flux-return yoke outside the solenoid. A more detailed description of the CMS detector, together with a definition of the coordinate system used and the relevant kinematic variables, can be found in Ref. [28].

Events are selected using a two-level trigger system [29]. The first level, composed of custom hardware processors, uses information from the calorimeters and muon detectors to select events of interest at a rate of around 100 kHz. The second level, composed of a high-level processor farm, decreases the event rate to around 1 kHz before data storage.

For the present analysis, events in the search regions are collected with a trigger that requires \(p_T^{\text{miss}} > 100\) GeV and \(H_T^{\text{miss}} > 100\) GeV, where \(H_T^{\text{miss}}\) is the magnitude of the vector \(p_T\) sum of jets reconstructed at the trigger level. This trigger is fully efficient after application of the event selection criteria described below.

IV. EVENT RECONSTRUCTION

Events are reconstructed using the particle-flow (PF) algorithm [30], which reconstructs charged hadrons, neutral hadrons, photons, electrons, and muons using information from all subdetectors. Electron and muon candidates are subjected to additional requirements [31,32] to improve their purity, and are further required to have \(p_T > 10\) GeV and to originate from within 2 mm of the beam axis in the transverse plane. Electron (muon) candidates must appear within \(|\eta| < 2.5\) (2.4). The missing transverse momentum \(p_T^{\text{miss}}\) in an event is given by the negative of the vector \(p_T\) sum of all reconstructed objects. Its magnitude is denoted \(p_T^{\text{miss}}\).

All photons and neutral hadrons in an event, together with charged particles that originate from the primary interaction vertex, are clustered into jets using the anti-
\(k_T\) algorithm with a distance parameter of 0.4 (AK4) [33]. The jets must satisfy a set of jet identification criteria as specified in Ref. [34]. Neutral particles from overlapping \(p\bar{p}\) interactions (“pileup”) are subtracted on an event-by-event basis using the FastJet technique [35,36]. Jets are corrected using factors from simulation to account for detector response as a function of jet \(p_T\) and \(\eta\). Additional corrections account for residual differences between simulation and data for the jet energy and momentum scales [37]. Only jets with \(p_T > 30\) GeV and either \(|\eta| < 2.4\) (tight) or \(|\eta| < 5.0\) (loose) are retained. The number of jets \(N_j\) in an event is defined to be the number of tight AK4 jets. The \(H_T\) variable is given by the scalar sum of jet \(p_T\) over this same jet sample.

Bottom quark jets are identified (b tagged) by applying the combined secondary vertex algorithm (CSVv2) [38,39] at the medium working point to tight AK4 jets. The b quark identification efficiency ranges from 60 to 70% for jet \(p_T\) between 20 and 400 GeV. The probability for a jet originating from a gluon or light-flavored quark to be b tagged, averaged over the jets in a sample of \(t\bar{t}\) events, is 1.4% [38].

In addition to AK4 jets, we define AK8 jets, constructed by clustering PF objects using the anti-
\(k_T\) algorithm with a distance parameter of 0.8. The AK8 jets are used in the top quark reconstruction procedure, described in Sec. VII. Pileup contributions to AK8 jets are accounted for using the “pileup per particle identification” [40,41] method, by which each charged and neutral particle is weighted by a factor representing its probability to originate from the primary interaction vertex before the clustering is performed. The AK8 jets are required to satisfy \(p_T > 200\) GeV.

V. LEPTON AND TRACK VETOES

To obtain an all-hadronic event sample, events with isolated electrons or muons are vetoed. The isolation of electron and muon candidates is defined as the scalar \(p_T\) sum of PF candidates in a cone of radius \(\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}\) around the candidate’s trajectory, where \(\phi\) is the azimuthal angle and the sum excludes the electron or muon candidate. The cone size is 0.2 for \(p_T \leq 50\) GeV, 0.05 for \(p_T \geq 200\) GeV, and decreases in inverse proportion to the lepton \(p_T\) for \(50 < p_T < 200\) GeV. This decrease in cone size with increasing lepton \(p_T\) accounts for the greater collimation of a heavy object’s decay products as its Lorentz boost increases. The isolation sum is corrected for contributions from pileup using an estimate of the pileup energy in the cone [35]. Electron and muon candidates are considered to be isolated if their relative isolation, i.e., the ratio of the isolation sum to the candidate \(p_T\), is less than 0.1 and 0.2, respectively.

Events that survive the lepton veto are subjected to an isolated charged-particle track veto. This veto suppresses events with a hadronically decaying \(\tau\) lepton or with an isolated electron or muon not identified as such. Tracks considered for this veto must have \(p_T > 5\) GeV, \(|\eta| < 2.5\), and relative track isolation less than 0.2. The relative track isolation is defined analogously to the relative isolation of electrons and muons but is computed using charged PF candidates only, that appear within a fixed cone of
\( \Delta R = 0.3 \) around the track. To preserve signal efficiency, the isolated-track veto is applied only if the transverse mass \( m_{T} \) [42] of the isolated track-\( p_{T}^{\text{miss}} \) system is consistent with \( W \) boson decay, namely \( m_{T} < 100 \text{ GeV} \). The isolated-track veto reduces background from events with a leptonically decaying \( W \) boson by about 40%.

Following application of the above two vetoes, a significant fraction of the remaining SM background arises from events with a hadronically decaying \( \tau \) lepton (\( \tau_{h} \)). A charged-hadron veto is applied to reduce this background. The charged-hadron veto eliminates events that contain an isolated PF charged hadron with \( p_{T} > 10 \text{ GeV} \), \( \mid \eta \mid < 2.5 \), and \( m_{T} < 100 \text{ GeV} \). To be considered isolated, the relative isolation of the charged hadron, defined as in the previous paragraph, must be less than 0.1.

VI. EVENT SIMULATION

Samples of Monte Carlo (MC) simulated events are used to study the properties of signal and background processes. The MadGraph5_aMC@NLO 2.2.2 [43,44] event generator at leading-order (LO) is used to describe signal events and the SM production of \( t\bar{t}, W + \text{jets} \) (with \( W \rightarrow \ell \nu \)), \( Z + \text{jets} \) (with \( Z \rightarrow \nu \bar{\nu} \)), Drell–Yan (DY) + jets, and QCD multijet events. The \( t\bar{t} \) events are generated with up to three additional partons present beyond those that participate in the hard scattering, the signal events with up to two, and the other processes with up to four. The DY + jets events, specifically events with the decay of a real or virtual \( Z \) boson to a \( \mu^{+}\mu^{-} \) pair, are used as part of the procedure to evaluate background (Sec. IX B). The generation of these processes is based on LO parton distribution functions (PDFs) from NNPDF3.0 [45]. Single top quark events in the \( t\bar{t}W \) channel are generated with the next-to-leading order (NLO) Powheg v2.0 [46–49] program. The following rare SM processes are considered: \( t\bar{t}Z, t\bar{t}W, \text{triboson}, \) and \( t\bar{t}H \) production, generated at NLO with the MadGraph5_aMC@NLO 2.2.2 [43,50] program using NLO NNPDF3.0 PDFs; WZ and ZZ production, generated either with this same program or with the Powheg program mentioned in the previous sentence depending on the decay mode; and WW production, generated with the Powheg program mentioned in the previous sentence. Parton showering and hadronization are simulated for all MC samples with the Pythia v8.205 [51] program, which uses the underlying event tune CUE8T8M1 [52].

For simulated background processes, the CMS detector response is based on the Geant4 package [53]. Because of the intense computational requirements, the detector response for simulated signal events is performed with a fast simulation [54], which is tuned to provide results that are consistent with those from the Geant4-based simulation. For all MC samples, event reconstruction is performed in the same manner as for the data. The signal production cross sections are calculated using NLO plus next-to-leading logarithm (NLL) calculations [55]. The most precise cross section calculations currently available are used to normalize the SM simulated samples, corresponding to NLO or next-to-NLO accuracy in most cases [43,56–62].

The simulated events are corrected for differences between simulation and data in the \( b \) tagging efficiency, the top quark tagging (Section VII) efficiency, and the electron and muon identification and isolation selection efficiencies. The corrections for the \( b \) tagging efficiency are derived from multijet- and \( t\bar{t}\)-enriched event samples and are parameterized in terms of the jet kinematics [38]. The corrections for the top quark tagging efficiency are derived from a single-muon \( t\bar{t}\)-enriched control sample and are applied as a function of top quark \( p_{T} \). The corrections for the electron and muon identification and isolation efficiencies are determined from \( Z \rightarrow \ell\ell \) events.

Simulated \( t\bar{t} \) and signal events are corrected with scale factors to account for imperfect modeling of initial-state radiation (ISR). The ISR corrections are derived from a \( t\bar{t}\)-enriched control sample containing two leptons (ee, \( \mu\mu \), or \( e\mu \)) and two tagged \( b \) jets, and are applied as a function of \( \Delta N_{\text{ISR}}^{\text{jet}} \) up to \( N_{\text{jet}} = 6 \), where \( N_{\text{jet}} \) is the number of jets in the event other than the two that are \( b \) tagged. The correction is validated by applying it to simulation in a \( t\bar{t}\)-dominated single-lepton control sample covering various regions of phase space, including regions with a large number of jets. Agreement with data on the level of 20% of the correction is found in this control sample for key observables such as the distribution in the number of jets. To account for possible differences between \( t\bar{t} \) and signal events, a conservative uncertainty of 50% of the correction is assigned to the scale factors, both as applied to \( t\bar{t} \) and signal processes.

VII. TOP QUARK RECONSTRUCTION

The top quark tagging algorithm is the central feature of our analysis. It is designed to provide high reconstruction efficiency over the full range of top quark \( p_{T} \) in the considered signal models. A common strategy [63,64] for tagging hadronically decaying top quarks is to cluster jets with the AK8 algorithm and then to test whether the jet is consistent with having three subjets, as expected for the \( t \rightarrow bq\bar{q}' \) decay of a highly Lorentz-boosted top quark. Although these algorithms are efficient at large top quark \( p_{T} \), for \( p_{T} < 400 \text{ GeV} \) top quarks are more efficiently reconstructed by combining three individual AK4 jets, an approach known as “resolved” top quark tagging. To obtain high reconstruction efficiency over a wide range of top quark \( p_{T} \), we employ both types of algorithms and, in addition, consider top quark decays in which the decay products of the \( W \) boson are contained within an AK8 jet. To fully reconstruct the top quark in the latter case, an AK8 jet corresponding to the \( W \) boson decay is combined with an AK4 jet.
To identify high-\(p_T\) top quarks, AK8 jets with \(p_T > 400\text{ GeV}\) are selected. The mass of the jet is corrected with the soft-drop method [65,66] using angular exponent \(\beta = 0\), soft cutoff threshold \(z_{\text{cut}} < 0.1\), and characteristic radius \(R_0 = 0.8\), where the values of \(\beta\), \(z_{\text{cut}}\), and \(R_0\) are those recommended in Ref. [67] for AK8 jets. The soft-drop algorithm reclusters the AK8 jet into subjets using the Cambridge–Aachen algorithm [68,69]. This reclustering removes soft radiation, which can bias the jet mass determination. To be considered as a top quark candidate, the soft-drop mass must lie between 105 and 210 GeV. The \(N\)-subjettiness variables \(\tau_N\) [70] are used to determine the consistency of the jet with having three subjets. More details on this algorithm can be found in Ref. [63]. To be consistent with having three subjets, the requirement \(\tau_3/\tau_2 < 0.65\) is imposed. This requirement is made on the basis of optimization studies [67].

To avoid overlap between the top-tagged AK8 jets (denoted “monojets”) and the AK4 jets that are used to reconstruct resolved (“dijets”) or partially merged (“trijets”) top quarks, AK4 jets matched to the top-tagged AK8 jet are removed from the list of AK4 jets used in the reconstruction of the dijet and trijet categories. An AK4 jet is considered matched if it lies within \(\Delta R < 0.4\) of one of the soft-drop subjets of the tagged AK8 jet.

For the dijet category of top quark decays, we employ a similar technique to identify the jet from the hadronic \(W\) boson decay. An AK8 jet with \(p_T > 200\text{ GeV}\) must have a soft-drop corrected mass between 65 and 100 GeV. To be consistent with having two subjets, the requirement \(\tau_2/\tau_1 < 0.6\) is imposed. This requirement corresponds to the “high-purity pruning” criterion of Ref. [67]. The AK8 jet is combined with a loose AK4 jet to form a top quark candidate. The candidate must have a mass between 100 and 250 GeV, both jets must appear within a cone of radius \(\Delta R = 1\) around the direction of their summed \(p_T\) vector, and the ratio of the soft-drop corrected AK8 jet mass to the top quark candidate mass must lie between 0.85\((m_W/m_t)\) and 1.25\((m_W/m_t)\), with \(m_W\) the \(W\) boson mass. If more than one top quark candidate is found using the same AK8 jet, the combination with mass closest to \(m_t\) is chosen. The AK4 jet used to form the top quark candidate, and all AK4 jets matched to within \(\Delta R < 0.4\) of the soft-drop subjets from the AK8 jet, are removed from the list used to reconstruct the trijet category.

The trijet sample of top quark candidates is formed by combining three loose AK4 jets. The three jets must appear within a cone of radius \(\Delta R = 1.5\) around the direction of their summed \(p_T\) vector, no more than one of the three jets can be \(b\) tagged, and the trijet mass must lie between 100 and 250 GeV. The cone size is chosen to be \(\Delta R = 1.5\) because the background becomes very large for larger \(\Delta R\) values. The final trijet top quark sample is defined by applying the results of a random forest boosted decision tree [71] to the selected combinations. The random forest is trained with simulation using trijet combinations that satisfy the above criteria. Simulated samples of \(t\bar{t}\) and \(Z(\nu\bar{\nu}) + \text{jets}\) events are used for this purpose. In the \(t\bar{t}\) simulation, one top quark decays hadronically and the other semileptonically. Signal top quarks are defined as trijet combinations in the \(t\bar{t}\) simulation for which each of the three jets is matched to a distinct generator-level hadronically decaying top quark decay product within \(\Delta R < 0.4\), and whose overall momentum is matched to the generator-level top quark momentum within \(\Delta R < 0.6\). Background combinations are defined as trijet combinations in the \(t\bar{t}\) sample with no jet matched to a generator-level hadronically decaying top quark decay product, and as trijet combinations in the \(Z(\nu\bar{\nu}) + \text{jets}\) sample. If more than one background combination is found in an event, all combinations are used.

The variables considered in the random forest algorithm are the mass of the trijet system, the mass of each dijet combination, the angular separation and momenta of the jets in the trijet rest frame, the \(b\) tagging discriminator value of each jet, and the quark-versus-gluon-jet discriminator [72] value of each jet. To reduce correlations with the top quark \(p_T\) and thus to prevent overtraining in this variable, the \(p_T\) spectra of signal and background triplet combinations are flattened through reweighting. The random forest performance is improved by replacing the kinematic variables in the laboratory frame with their equivalents in the trijet rest frame, and by sorting jets according to their momenta in the trijet rest frame so that the highest (lowest) momentum jet is most (least) likely to originate from a \(b\) quark.

Tritop top quark candidates are selected by requiring the random forest discriminator value to exceed 0.85. This value is chosen based on optimization studies involving the full limit-setting procedure described in Sec. X. If two or more selected trijets share one or more AK4 jets, only the combination with the largest discriminator value is retained.

All top quark candidates must have \(|\eta| < 2.0\). The final set consists of the nonoverlapping candidates from the three reconstruction categories. The total efficiency of the algorithm, including a breakdown into the three categories, is shown in Fig. 2. The efficiency is determined using T2tt signal events with a top squark mass of 850 GeV and an LSP mass of 100 GeV, based on the number of generator-level hadronically decaying top quarks that are matched to a reconstructed top quark candidate divided by the total number of generator-level top quarks that decay hadronically. Similar results are found using SM \(t\bar{t}\) events. The matching between the generator-level and reconstructed top quarks requires the overall reconstructed top quark to be matched to the generator-level top quark within \(\Delta R < 0.4\). The misidentification rate varies between 15 and 22% as a function of \(p_T^{\text{miss}}\), with an average of about 20%, as determined using simulated \(Z(\nu\bar{\nu}) + \text{jets}\) events after
applying selection criteria similar to those used for the data (Sec. VIII): \( N_j \geq 4, N_b \geq 1, p_T^{\text{miss}} > 250 \) GeV, and no isolated electron or muon with \( p_T > 10 \) GeV.

Relative to Ref. [20], the top quark tagging algorithm has been improved by using AK8 jets for the monojet and dijet categories, rather than strictly AK4 jets, and through implementation of the random forest tree for the trijet category. These improvements provide a factor of two reduction in the top quark misidentification rate while maintaining a similar efficiency.

VIII. EVENT SELECTION AND SEARCH REGIONS

Our study is an inclusive search for events containing \( p_T^{\text{miss}} \) and reconstructed top quarks. The selection criteria are intended, in general, to be nonrestrictive, while still providing high trigger efficiency and sensitivity to a wide variety of new-physics scenarios. All events must satisfy filters designed to remove detector- and beam-related noise. The events are subjected to the lepton, isolated-track, and charged-hadron vetoes of Sec. V. To improve the rejection of background, the two tight AK4 jets with highest \( p_T \) must have \( p_T > 50 \) GeV. Events are required to have \( N_j \geq 4, N_b \geq 1, N_t \geq 1, p_T^{\text{miss}} > 250 \) GeV, and \( H_T > 300 \) GeV.

The QCD multijet background mostly arises when the \( p_T \) of one of the highest \( p_T \) jets is undermeasured, causing \( p_T^{\text{miss}} \) to be aligned with that jet. This undermeasurement can occur because of jet misreconstruction or, in the case of semileptonic \( b \) or \( c \) quark decays, an undetected neutrino. To reduce this background, requirements are placed on the azimuthal angle between \( p_T^{\text{miss}} \) and the three loose AK4 jets with highest \( p_T \), denoted \( j_1, j_2, \) and \( j_3 \) in order of decreasing \( p_T \). Specifically, we require \( \Delta \phi (p_T^{\text{miss}}, j_1) > 0.5, \Delta \phi (p_T^{\text{miss}}, j_2) > 0.5, \) and \( \Delta \phi (p_T^{\text{miss}}, j_3) > 0.3 \).

The \( m_T^2 \) variable [20–22] is used to reduce background from \( \bar{t}t \) events. This variable is designed to provide an estimate of the transverse mass of pair-produced heavy objects that decay to both visible and undetected particles. It has a kinematic upper limit at the mass of the heavy object undergoing decay. Thus the upper limit for SM \( \bar{t}t \) events is \( m_t \), while the upper limit for TeV-scale squarks and gluinos is much larger. If there are two tagged top quarks in an event, \( m_{T2} \) is calculated using the pair of tagged top quarks and \( p_T^{\text{miss}} \). If there are more than two tagged top quarks, we compute \( m_{T2} \) for all combinations and choose the combination with the smallest \( m_{T2} \). If there is only one tagged top quark, we construct a proxy for the other top quark using the highest \( p_T \) b tagged jet as a seed. If a b tagged jet is not available, because there is only one b tagged jet in the event and it is part of the reconstructed top quark, the highest \( p_T \) jet is used as the seed. The seed jet is combined with a loose AK4 jet to define the top quark proxy if the resulting pair of jets has a mass between 50 and 220 GeV and if the two jets appear within \( \Delta R = 1.5 \) of each other; otherwise the seed jet by itself is used as the top quark proxy. The proxy is combined with the tagged top quark and \( p_T^{\text{miss}} \) to determine \( m_{T2} \). Irrespective of the number of tagged top quarks, we require \( m_{T2} > 200 \) GeV.

The search is performed in 84 nonoverlapping search regions. Regions with \( N_b \leq 2 \) and \( N_t \leq 2 \) use \( N_b, N_t, p_T^{\text{miss}}, \) and \( m_{T2} \) as the binned search variables. Regions with \( N_b \geq 3 \) or \( N_t \geq 3 \) use \( N_b, N_t, p_T^{\text{miss}}, \) and \( H_T \). The reason \( H_T \) is used for these latter regions, and not \( m_{T2} \), is that in events with many jets, the jets from the decay of a particular heavy object may not always be correctly associated with that object, causing the distribution of \( m_{T2} \) to be broad and relatively flat. We find that \( H_T \) provides better discrimination between signal and background for \( N_b \geq 3 \) or \( N_t \geq 3 \). The 84 regions in \( m_{T2} \) versus \( p_T^{\text{miss}} \) or in \( H_T \) versus \( p_T^{\text{miss}} \) are illustrated in Fig. 3. The boundaries between the regions were determined through sensitivity studies.

To simplify use of our data by others, we also define 10 aggregate search regions, specified in Table I. The aggregate regions are nonexclusive and are intended to be considered independently. The first four aggregate regions represent topologies of general interest. The fifth and sixth are sensitive to direct top squark pair production. The seventh region targets the large \( \Delta m (\tilde{g}, \tilde{\chi}_1^0) \) region of T5ttcc-like models, while the final three target events with a large number of top quarks such as are produced in the T11tttt and T5tttt models.

IX. BACKGROUND ESTIMATION

We next discuss the evaluation of the SM background. A change relative to Ref. [20] is that we now use a translation...
factor method, as described in Sec. IX A, to evaluate the background from $t\bar{t}$, single top quark, and $W^+ + \text{jets}$ events. In Ref. [20] we rather used $\tau_h$ response templates and separately evaluated terms constructed from the electron and muon acceptance, isolation efficiency, and reconstruction-and-identification efficiency to evaluate this background. The reason for the change is to simplify the modeling of variables for the AK8 jets and for the random forest decision tree now used in the top quark tagging algorithm. Another change is that the "loose" dimuon control sample described in Sec. IX B is selected using more restrictive requirements, as is allowed by the larger data sample now available, leading to reduced systematic uncertainties.

A. Background from $t\bar{t}$, single top quark, and $W^+ + \text{jets}$ events

The largest background, accounting for about 70% of the total background integrated over the 84 search regions, is due to $t\bar{t}$, single top quark, and $W^+ + \text{jets}$ events with a leptonically decaying $W$ boson. This background arises in one of two distinct ways. First, if the $W$ boson decays to a $\tau$ lepton that decays hadronically, the $\tau$ lepton can be...
reconstructed as a jet and the event can escape the vetoes of Sec. V. Second, if the W boson decays to an electron or muon (including from the decay of a τ lepton) that is not reconstructed or identified, is not isolated, or lies outside the acceptance of the analysis, the event can escape the vetoes. These two possibilities are referred to as the τb and lost-lepton backgrounds, respectively. They are evaluated, together, using a single-lepton data control sample (CS) collected using the same trigger that is used to collect signal events. The CS events must satisfy the same criteria as the data except for the vetoes of Sec. V, which are replaced by a requirement that there be exactly one isolated electron or muon candidate based on the isolation criteria of Sec. V. To reduce potential contributions from signal processes, CS events must have $m_T < 100 \text{ GeV}$.

The predicted summed number of $\tau_b$ and lost-lepton events in a search region is given by the number of single-electron or single-muon events in the corresponding region of the CS, multiplied by a translation factor from simulation. Predictions from the single-electron and single-muon samples are determined separately and used as independent constraints in the likelihood fit described in Sec. X. The translation factor is given by the ratio of the summed number of simulated $\tau_b$ and lost-lepton events in the search region to the number of simulated single-electron or single-muon events in the corresponding CS region.

The method is tested using an orthogonal data sample, referred to as the “sideband” (SB), selected using the same criteria as are applied to the data except with $N_t = 0$, $N_b \geq 2$, and $\Delta \phi (p_T^{\text{miss}}, \ell_1, \ell_2, \ell_3) > 0.5$, where the last two requirements reduce contributions from $Z(\nu \bar{\nu}) + \text{jets}$ and QCD multijet events. The SB, which is enhanced in events with semileptonic top quark decays, is divided into four intervals of $p_T^{\text{miss}}$. The contribution of $\tau_b$ and lost-lepton events to the intervals is determined in an analogous manner to that described above for the search regions, namely by multiplying the number of events in the corresponding interval of the single-electron or single-muon CS by a translation factor from simulation, defined analogously to the translation factors of the standard analysis. The contributions of $Z + \text{jets}$, QCD multijet, and rare events to the SB are taken directly from simulation.

Figure 4 shows the $p_T^{\text{miss}}$ distribution in the SB in comparison to the SM prediction. The histogram labeled “$t\bar{t}/tW$” shows the predicted contribution from $\tau_b$ and lost-lepton events. The total SM prediction is seen to agree with the data within the uncertainties, providing a validation for the translation factor procedure.

Systematic uncertainties in the prediction for the $t\bar{t}$, single top quark, and $W + \text{jets}$ background are evaluated from the following sources, based on the uncertainties in the respective quantities: the statistical uncertainty in the translation factors ($1-40\%$ depending on the search region), the lepton reconstruction and isolation efficiency ($7-43\%$), the jet and $p_T^{\text{miss}}$ energy scale and resolution (up to $64\%$), the ISR modeling (up to $13\%$), the PDFs (up to $32\%$), and the $b$ jet tagging efficiency ($1\%$).

As a cross-check, the lost-lepton background is evaluated using a complementary procedure, described in Ref. [20], based on the single-lepton CS described above and on factors obtained for each search region from $t\bar{t}$, single top quark, and $W + \text{jets}$ simulation that account for the acceptance, the isolation efficiency, and the reconstruction-and-identification efficiency. The lost-lepton background evaluated with this approach is consistent with that obtained from the translation factor method.

### B. Background from $Z(\nu \bar{\nu}) + \text{jets}$ events

The background from $Z(\nu \bar{\nu}) + \text{jets}$ events is evaluated using simulated $Z(\nu \bar{\nu}) + \text{jets}$ events that satisfy the search region selection criteria. Two corrections, derived from an event sample enhanced in $DY(Z \rightarrow \mu \mu) + \text{jets}$ production, are applied to account for differences between data and

| Region | $N_t$ | $N_b$ | $m_T$ [GeV] | $p_T^{\text{miss}}$ [GeV] | Motivation |
|--------|-------|-------|-------------|------------------------|------------|
| 1      | $\geq 1$ | $\geq 1$ | $\geq 200$ | $\geq 250$ | Events satisfying selection criteria |
| 2      | $\geq 2$ | $\geq 2$ | $\geq 200$ | $\geq 250$ | Events with $N_t \geq 2$ and $N_b \geq 2$ |
| 3      | $\geq 3$ | $\geq 1$ | $\geq 200$ | $\geq 250$ | Events with $N_t \geq 3$ and $N_b \geq 1$ |
| 4      | $\geq 3$ | $\geq 3$ | $\geq 200$ | $\geq 250$ | $T1ttb$; small $\Delta m(\tilde{g}, \tilde{\chi}^0_1)$ and $m_{\tilde{t}_1} < m_t$ |
| 5      | $\geq 2$ | $\geq 1$ | $\geq 200$ | $\geq 400$ | $T2tt$; small $\Delta m(\tilde{t}, \tilde{\chi}^0_1)$ |
| 6      | $\geq 1$ | $\geq 2$ | $\geq 600$ | $\geq 400$ | $T2tt$; large $\Delta m(\tilde{t}, \tilde{\chi}^0_1)$ |

| Region | $N_t$ | $N_b$ | $H_T$ [GeV] | $p_T^{\text{miss}}$ [GeV] | Motivation |
|--------|-------|-------|-------------|------------------------|------------|
| 7      | $\geq 1$ | $\geq 2$ | $\geq 1400$ | $\geq 500$ | $T1ttbb$ & $T5ttcc$; large $\Delta m(\tilde{g}, \tilde{\chi}^0_1)$ |
| 8      | $\geq 2$ | $\geq 3$ | $\geq 600$ | $\geq 350$ | $T1ttt$; small $\Delta m(\tilde{g}, \tilde{\chi}^0_1)$ |
| 9      | $\geq 2$ | $\geq 3$ | $\geq 300$ | $\geq 500$ | $T1/T5ttt$ & $T1ttbb$; intermediate $\Delta m(\tilde{g}, \tilde{\chi}^0_1)$ |
| 10     | $\geq 2$ | $\geq 3$ | $\geq 1300$ | $\geq 500$ | $T1/T5tt$; large $\Delta m(\tilde{g}, \tilde{\chi}^0_1)$ |
The trigger to select the DY + jets events requires that there be at least one muon with $p_T > 50$ GeV, while the offline selection requires two oppositely charged muons with a dimuon invariant mass between 81 and 101 GeV, and the highest (second-highest) $p_T$ muon in the event to have $p_T > 50(20)$ GeV. The dimuon system is removed from the events to emulate $\vec{p}_{T}^{\text{miss}}$ in $Z(\nu\bar{\nu}) + \text{jets}$ events.

The first correction, which accounts for the $N_j$ distribution, is based on a “loose” dimuon control sample selected by imposing, on the DY-enhanced event sample described in the previous paragraph, the same requirements on $\Delta\phi(p_T^{\text{miss}}, j_{1,2,3})$, $H_T$, and $N_j$ as are applied to signal candidate events, but with less stringent requirement $p_T^{\text{miss}} > 100$ GeV and with no requirement on $N_b$. The correction is determined as a function of $N_j$ as the ratio of the number of events in the loose control sample, with non-DY events subtracted using simulation, to the number of events in a similarly selected sample of simulated DY events. The corrections are applied to the $Z(\nu\bar{\nu}) + \text{jets}$ simulation as weights based on the value of $N_j$.

The second correction adjusts the overall normalization of the simulated $Z(\nu\bar{\nu}) + \text{jets}$ sample. It is derived from a...
“tight” dimuon data control sample selected by applying, to
the DY-enhanced event sample described in the first para-
dograph of this section, the same requirements as are applied
to signal events except, of the vetoes described in Sec. V,
only the veto on isolated electrons is applied, and there is
no requirement on $N_{b}$. The correction is given by the ratio
of the number of events in the tight control sample, with
non-DY backgrounds subtracted using simulation, to the
number of events in a sample of simulated DY events
selected with the same criteria.

Systematic uncertainties in the prediction for the
\(Z(\nu \bar{\nu}) + \text{jets}\) background are derived from the shape
differences between data and simulation in the loose
dimuon control sample as a function of $N_{b}$, $N_{t}$, $p_{T}^{\text{miss}}$, $m_{T2}$, and $H_{T}$ after the first correction described above has
been applied. As examples, the post-correction compar-
isons between data and simulation for the $p_{T}^{\text{miss}}$ and $N_{b}$
distributions are shown in Fig. 5. The shift in the central
value between the data and simulation in the distributions
is used to define an additional uncertainty, which varies
between 14 and 44% depending on the search region.
The statistical uncertainty in the $N_{t}$ shape correction
(1%–46%) and in the overall normalization correction
(7.6%) are also taken as systematic uncertainties.
Additional systematic uncertainties account for the jet
and $p_{T}^{\text{miss}}$ energy scales (1%–71%), the $b$ tagging effi-
ciency (1%–23%), the PDFs and the renormalization and
factorization scales (1%–48%), the statistical uncertainty
in the simulation (1%–81%, with the results for a few
search regions as high as 100%), and the trigger (up
to 14%).

C. Background from multijet events
The background from QCD multijet events is evalu-
ated similarly to the background from $t\bar{t}$, single top
quark, and $W + \text{jets}$ events. A QCD data control sample
is defined using the same trigger and selection criteria
as are used to select signal events but with the less
restrictive condition $p_{T}^{\text{miss}} > 200$ GeV and with the
selection criteria on $\Delta\phi(p_{T}^{\text{miss}}, j_{1,2,3})$ inverted. This
yields a signal-depleted control sample dominated by
QCD multijet events. The predicted number of QCD
multijet events in each of the 84 search regions is given
by the yield in the corresponding region of the QCD
control sample, after contributions from non-QCD SM
processes have been subtracted using simulation, multi-
plied by a translation factor derived from simulated
QCD multijet events. The translation factors are applied
as a function of $p_{T}^{\text{miss}}$ and $m_{T2}$ for $N_{b}$ and $N_{t} \leq 2$, and
as a function of $p_{T}^{\text{miss}}$ for $N_{b}$ or $N_{t} \geq 3$, and are
normalized to data in the $200 < p_{T}^{\text{miss}} < 250$ GeV
region of the QCD control sample.

A systematic uncertainty in the QCD multijet prediction
for each search region is evaluated as the difference
between the event yield obtained directly from the QCD
multijet simulation for that region and the prediction
obtained by applying the background prediction procedure
to simulated QCD multijet samples (30%–500%).
Additional sources of uncertainty are from the statistical
uncertainty in the translation factors (30%–300%) and the
subtraction of the non-QCD-multijet SM contributions to
the QCD control sample (2%–50%).

FIG. 6. Observed event yields (black points) and prefit SM background predictions (filled solid areas) for the 84 search regions, where “prefit” means there is no constraint from the likelihood fit. The lower panel shows the ratio of the data to the total background prediction. The hatched bands correspond to the total uncertainty in the background prediction.
D. Background from rare processes

Background from rare events forms only a small fraction of the total background and can be dominant, however, in search regions where the corresponding regions of the single-electron, single-muon, and QCD data control samples, that account for the background predictions and signal yields. The uncertainties are treated as nuisance parameters with log-normal probability density functions. Correlations between search regions are taken into account. Upper limits at 95% confidence level (CL) on the SUSY production cross sections are calculated using a modified frequentist approach with the CLs criterion [73,74] and asymptotic results for the test statistic [75,76]. Signal models for which the 95% CL upper limit on the production cross section falls below the theoretical cross section (based on NLO + NLL calculations [55]) are considered to be excluded by the analysis.

The uncertainties in the signal modeling are determined individually for each search region and account for the following sources: the statistical uncertainty in the simulated event samples, the integrated luminosity (2.5% [77]), the lepton and isolated-track veto efficiencies (up to 6.8%), the $b$ tagging efficiency (up to 21%), the trigger efficiency (up to 2.6%), the renormalization and factorization scales (up to 3.5%), the ISR modeling (up to 46%), the jet energy scale corrections (up to 34%), the top quark reconstruction efficiency (up to 14%), and the modeling of the fast simulation compared with the full simulation for top quark production. The number of observed events and the predicted background predictions (filled solid areas) for the 10 aggregate search regions are summarized in Fig. 6. Numerical values are given in Tables II–IV of Appendix. The corresponding results for the aggregate search regions are presented in Fig. 7, with numerical values in Table V of Appendix. No statistically significant deviation between the data and the background predictions is observed. The largest source of deviation between the data and the background predictions is from the $t\bar{t}Z$ production. To validate the $t\bar{t}Z$ cross section in the simulation, a three-lepton control sample is selected. The yields of events in this sample between simulation and data are found to agree within the statistical uncertainty of 30%, which is taken as the systematic uncertainty in the $t\bar{t}Z$ background estimate.

X. RESULTS AND INTERPRETATION

The number of observed events and the predicted number of SM background events in each of the 84 search regions are summarized in Fig. 6. Numerical values are given in Tables II–IV of Appendix. The corresponding results for the aggregate search regions are presented in Fig. 7, with numerical values in Table V of Appendix. No statistically significant deviation between the data and the background predictions is observed. The largest source of background typically arises from $t\bar{t}$ or $W +$ jets production, followed by $Z(\nu\bar{\nu}) +$ jets production. The latter background source can be dominant, however, in search regions with a high $p_T^{\text{miss}}$ threshold. The contributions of the QCD multijet and rare backgrounds are small in all regions.

Exclusion limits are derived for the signal models of Sec. II using a binned likelihood fit to the data. The likelihood function is given by the product of Poisson probability density functions, one for each search region and for each of the corresponding regions of the single-electron, single-muon, and QCD data control samples, that account for the background predictions and signal yields. The uncertainties are treated as nuisance parameters with log-normal probability density functions. Correlations between search regions are taken into account. Upper limits at 95% confidence level (CL) on the SUSY production cross sections are calculated using a modified frequentist approach with the CLs criterion [73,74] and asymptotic results for the test statistic [75,76]. Signal models for which the 95% CL upper limit on the production cross section falls below the theoretical cross section (based on NLO + NLL calculations [55]) are considered to be excluded by the analysis.

The uncertainties in the signal modeling are determined individually for each search region and account for the following sources: the statistical uncertainty in the simulated event samples, the integrated luminosity (2.5% [77]), the lepton and isolated-track veto efficiencies (up to 6.8%), the $b$ tagging efficiency (up to 21%), the trigger efficiency (up to 2.6%), the renormalization and factorization scales (up to 3.5%), the ISR modeling (up to 46%), the jet energy scale corrections (up to 34%), the top quark reconstruction efficiency (up to 14%), and the modeling of the fast simulation compared with the full simulation for top quark production. The number of observed events and the predicted background predictions (filled solid areas) for the 10 aggregate search regions are summarized in Fig. 6. Numerical values are given in Tables II–IV of Appendix. The corresponding results for the aggregate search regions are presented in Fig. 7, with numerical values in Table V of Appendix. No statistically significant deviation between the data and the background predictions is observed. The largest source of deviation between the data and the background predictions is from the $t\bar{t}Z$ production. To validate the $t\bar{t}Z$ cross section in the simulation, a three-lepton control sample is selected. The yields of events in this sample between simulation and data are found to agree within the statistical uncertainty of 30%, which is taken as the systematic uncertainty in the $t\bar{t}Z$ background estimate.

The largest source of background typically arises from $t\bar{t}$ or $W +$ jets production, followed by $Z(\nu\bar{\nu}) +$ jets production. The latter background source can be dominant, however, in search regions with a high $p_T^{\text{miss}}$ threshold. The contributions of the QCD multijet and rare backgrounds are small in all regions.

Exclusion limits are derived for the signal models of Sec. II using a binned likelihood fit to the data. The likelihood function is given by the product of Poisson probability density functions, one for each search region and for each of the corresponding regions of the single-electron, single-muon, and QCD data control samples, that account for the background predictions and signal yields. The uncertainties are treated as nuisance parameters with log-normal probability density functions. Correlations between search regions are taken into account. Upper limits at 95% confidence level (CL) on the SUSY production cross sections are calculated using a modified frequentist approach with the CLs criterion [73,74] and asymptotic results for the test statistic [75,76]. Signal models for which the 95% CL upper limit on the production cross section falls below the theoretical cross section (based on NLO + NLL calculations [55]) are considered to be excluded by the analysis.

The uncertainties in the signal modeling are determined individually for each search region and account for the following sources: the statistical uncertainty in the simulated event samples, the integrated luminosity (2.5% [77]), the lepton and isolated-track veto efficiencies (up to 6.8%), the $b$ tagging efficiency (up to 21%), the trigger efficiency (up to 2.6%), the renormalization and factorization scales (up to 3.5%), the ISR modeling (up to 46%), the jet energy scale corrections (up to 34%), the top quark reconstruction efficiency (up to 14%), and the modeling of the fast simulation compared with the full simulation for top quark production.
reconstruction and mistagging (up to 24%). All uncertainties except those from the statistical precision of the simulation are treated as fully correlated between search regions. Signal contamination, namely potential contributions of signal events to the control samples, is taken into account when computing the limits. Note that signal contamination is significant only for the single-lepton control samples of Sec. IX A and is negligible for the dimuon and inverted-$\Delta \phi$ control samples of Secs. IX B and IX C.

Figure 8 shows the 95% CL exclusion limits obtained for the T2tt model of direct top squark pair production: top squark masses up to 1020 GeV and LSP masses up to 430 GeV are excluded. The results for the four models of gluino pair production, T1tttt, T1ttbb, T5tttt, and T5ttcc, are shown in Fig. 9. Gluino masses up to 2040 GeV and LSP masses up to 1150 GeV are excluded for the T1tttt model, with corresponding limits of 2020 and 1150 GeV for the T1ttbb model, 2020 and 1150 GeV for the T5tttt model, and 1810 and 1100 GeV for the T5ttcc model. The limits on the gluino mass are somewhat lower for the T1ttbb model than for the T1tttt model because of the smaller average number of top quarks. The lower limit

\[
\text{FIG. 9. The 95\% CL upper limit on the production cross section of the T1tttt (upper left), T1ttbb (upper right), T5tttt (bottom left), and T5ttcc (bottom right) simplified models as a function of the gluino and LSP masses. The meaning of the curves is explained in the Fig. 8 caption. Limits are not given for the T5tttt model for } m_{\tilde{\chi}}^0 < 50 \text{ GeV for the reason stated in the text.}
\]
of up to 2040 GeV obtained for the gluino mass in the T1tttt model improves the corresponding limits of Refs. [17,18] by around 100 GeV, while the limit on the gluino mass of up to 1810 GeV obtained for the T5ttcc model improves that presented in Ref. [78] by 560 GeV. This emphasizes the effectiveness of top quark tagging in all-hadronic events as a means to search for new physics that yields top quarks, and the complementarity of our study with respect to searches based on other signatures.

In the case of the T5tttt model there is a significant degradation of the exclusion limit as \( m_{\tilde{g}} \) approaches zero. This is a consequence of the kinematics of the \( \tilde{t} \rightarrow \tilde{\chi}_1^+ t \) decay, by which only a small portion of the top squark momentum is transferred to the LSP if the LSP is lighter than the top quark. The events then have very small \( p_T^{\text{miss}} \) and a small selection efficiency. The correction to account for signal contamination becomes larger than the number of selected signal events and the statistical treatment to account for signal contamination becomes unreliable. For this reason, we do not present results for the T5tttt model if \( m_{\tilde{t}_1} < 50 \) GeV.

XI. SUMMARY

Results are presented from a search for direct and gluino-mediated top squark production in proton-proton collisions at a center-of-mass energy of 13 TeV. The centerpiece of the analysis is a top quark tagging algorithm that identifies hadronically decaying top quarks with high efficiency across a wide range of top quark transverse momentum \( p_T \). The search is based on all-hadronic events with at least four jets, at least one tagged top quark, at least one tagged bottom quark jet, and a large imbalance in transverse momentum \( p_T^{\text{miss}} \). The data correspond to an integrated luminosity of 35.9 fb\(^{-1}\) collected with the CMS detector at the LHC in 2016. A set of 84 search regions is defined based on \( p_T^{\text{miss}} \), the mass variable \( m_{t_2} \), the scalar \( p_T \) sum of jets \( H_T \), the number of tagged top quarks, and the number of tagged bottom quark jets. No statistically significant excess of events is observed relative to the expectation from the standard model.

Cross section upper limits at 95% confidence level are evaluated for a simplified model of direct top squark pair production, in which the top squarks decay to a top quark and the lightest supersymmetric particle (LSP) neutralino, and for simplified models of gluino pair production, in which the gluinos decay to final states containing top quarks and LSPs. Using the signal cross sections calculated with next-to-leading-order plus next-to-leading-logarithm accuracy, 95% confidence level lower limits are set on the masses of the top squark, the gluino, and the LSP. For the model of direct top squark pair production, top squark masses up to 1020 GeV and LSP masses up to 430 GeV are excluded. For the models of gluino pair production, gluinos with masses as large as 1810 to 2040 GeV are excluded, depending on the model, with corresponding exclusions for LSPs with masses as large as 1100 to 1150 GeV. These results significantly extend those of our previous study [20]. The use of top quark tagging provides a novel means to search for new phenomena at the LHC, yielding complementary sensitivity to other approaches.

ACKNOWLEDGMENTS

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centers and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: the Austrian Federal Ministry of Science, Research and Economy and the Austrian Science Fund; the Belgian Fonds de la Recherche Scientifique, and Fonds voor Wetenschappelijk Onderzoek; the Brazilian Funding Agencies (CNPq, CAPES, FAPERJ, and FAPESP); the Bulgarian Ministry of Education and Science; CERN; the Chinese Academy of Sciences, Ministry of Science and Technology, and National Natural Science Foundation of China; the Colombian Funding Agency (COLCIENCIAS); the Croatian Ministry of Science, Education and Sport, and the Croatian Science Foundation; the Research Promotion Foundation, Cyprus; the Ministry of Education and Research, Estonian Research Council via IUT23-4 and IUT23-6 and European Regional Development Fund, Estonia; the Academy of Finland, Finnish Ministry of Education and Culture, and Helsinki Institute of Physics; the Institut National de Physique Nucléaire et de Physique des Particules / CNRS, and Commissariat à l’Énergie Atomique et aux Énergies Alternatives / CEA, France; the Bundesministerium für Bildung und Forschung, Deutsche Forschungsgemeinschaft, and Helmholtz-Gemeinschaft Deutscher Forschungszentren, Germany; the General Secretariat for Research and Technology, Greece; the National Scientific Research Foundation, and National Innovation Office, Hungary; the Department of Atomic Energy and the Department of Science and Technology, India; the Institute for Studies in Theoretical Physics and Mathematics, Iran; the Science Foundation, Ireland; the Istituto Nazionale di Fisica Nucleare, Italy; the Ministry of Science, ICT and Future Planning, and National Research Foundation (NRF), Republic of Korea; the Lithuanian Academy of Sciences; the Ministry of Education, and University of Malaya (Malaysia); the Mexican Funding Agencies (CINVESTAV, CONACYT, SEP, and UASLP-FAI); the Ministry of Business, Innovation and Employment, New Zealand; the Pakistan Atomic Energy Commission; the Ministry of
Science and Higher Education and the National Science Centre, Poland; the Fundação para a Ciência e a Tecnologia, Portugal; JINR, Dubna; the Ministry of Education and Science of the Russian Federation, the Federal Agency of Atomic Energy of the Russian Federation, Russian Academy of Sciences, and the Russian Foundation for Basic Research; the Ministry of Education, Science and Technological Development of Serbia; the Secretaria de Estado de Investigación, Desarrollo e Innovación and Programa Consolider-Ingenio 2010, Spain; the Swiss Funding Agencies (ETH Board, ETH Zurich, PSI, SNF, UniZH, Canton Zurich, and SER); the Ministry of Science and Technology, Taipei; the Thailand Center of Excellence in Physics, the Institute for the Promotion of Teaching Science and Technology of Thailand, Special Task Force for Activating Research and the National Science and Technology Development Agency of Thailand; the Scientific and Technical Research Council of Turkey, and Turkish Atomic Energy Authority; the National Academy of Sciences of Ukraine, and State Fund for Fundamental Researches, Ukraine; the Science and Technology Facilities Council, UK; the US Department of Energy, and the US National Science Foundation. Individuals have received support from the Marie-Curie program and the European Research Council and EPLANET (European Union); the Leventis Foundation; the A.P. Sloan Foundation; the Alexander von Humboldt Foundation; the Belgian Federal Science Policy Office; the Fonds pour la Formation à la Recherche dans l’Industrie et dans l’Agriculture (FRIA-Belgium); the Agentschap voor Innovatie door Wetenschap en Technologie (IWT-Belgium); the Ministry of Education, Youth and Sports (MEYS) of the Czech Republic; the Council of Science and Industrial Research, India; the HOMING PLUS program of Foundation for Polish Science, cofinanced from European Union, Regional Development Fund; the Compagnia di San Paolo (Torino); the Consorzio per la Fisica (Trieste); MIUR project 20108T4XTM (Italy); the Thalis and Aristeia programs cofinanced by EU-ESF and the Greek NSRF; and the National Priorities Research Program by Qatar National Research Fund.

APPENDIX: PREFIT BACKGROUND PREDICTIONS

Tables II–IV present the prefitted predictions for the number of standard model background events in each of the 84 search regions, along with the number of observed events. “Prefit” means that there is no constraint from the likelihood fit. The corresponding information for the 10 aggregate search regions is presented in Table V.

| Search region | $N_t$ | $N_b$ | $m_{T2}$ [GeV] | $p_{T2}^{miss}$ [GeV] | Data | Predicted background |
|---------------|-------|-------|----------------|----------------------|------|---------------------|
| 1             | 1     | 1     | 200–300 GeV   | 250–400 GeV          | 1649 | $1600 \pm 30_{-140}^{+130}$ |
| 2             | 1     | 1     | 200–300 GeV   | 400–500 GeV          | 85   | $73^{+7.7}_{-6.9}$ |
| 3             | 1     | 1     | 200–300 GeV   | 500–600 GeV          | 23   | $18^{+3.4}_{-3}$ |
| 4             | 1     | 1     | 200–300 GeV   | 600–750 GeV          | 7    | $3.6^{+1.9}_{-0.8}$ |
| 5             | 1     | 1     | 200–550 GeV   | $\geq$750 GeV       | 7    | $5.0^{+2.4}_{-1.2}$ |
| 6             | 1     | 1     | 300–400 GeV   | 250–400 GeV          | 1020 | $890 \pm 20_{-80}^{+80}$ |
| 7             | 1     | 1     | 300–400 GeV   | 400–500 GeV          | 87   | $79^{+7.5}_{-6}$ |
| 8             | 1     | 1     | 300–400 GeV   | 500–600 GeV          | 23   | $17^{+4}_{-3}$ |
| 9             | 1     | 1     | 300–400 GeV   | 600–750 GeV          | 9    | $3.7^{+2.2}_{-0.8}$ |
| 10            | 1     | 1     | 400–550 GeV   | 250–400 GeV          | 108  | $107^{+5}_{-5}$ |
| 11            | 1     | 1     | 400–550 GeV   | 400–500 GeV          | 116  | $105^{+5}_{-5}$ |
| 12            | 1     | 1     | 400–550 GeV   | 500–600 GeV          | 47   | $38^{+5}_{-4}$ |
| 13            | 1     | 1     | 400–550 GeV   | 600–750 GeV          | 12   | $8.1^{+2.4}_{-1.2}$ |
| 14            | 1     | 1     | 550–750 GeV   | 250–400 GeV          | 7    | $0.7^{+1.0}_{-0.4}$ |
| 15            | 1     | 1     | 550–750 GeV   | 400–500 GeV          | 7    | $4.3^{+2.0}_{-1.1}$ |
| 16            | 1     | 1     | 550–750 GeV   | 500–600 GeV          | 17   | $13^{+3}_{-2}$ |
| 17            | 1     | 1     | 550–750 GeV   | 600–750 GeV          | 10   | $19^{+3}_{-2}$ |
| 18            | 1     | 1     | 550–750 GeV   | $\geq$750 GeV       | 7    | $4.0^{+1.5}_{-0.5}$ |
| 19            | 1     | 1     | $\geq$750 GeV | 250–600 GeV          | 0    | $0.1^{+1.7}_{-1}$ |
| 20            | 1     | 1     | $\geq$750 GeV | 600–750 GeV          | 1    | $1.9^{+2.2}_{-1.0}$ |
| 21            | 1     | 1     | $\geq$750 GeV | $\geq$750 GeV       | 8    | $4.6^{+1.6}_{-0.5}$ |
### TABLE III. The observed number of events and the total background prediction for search regions with \( N_t = 1 \) and \( N_b \geq 2 \). The first uncertainty in the background prediction is statistical and the second is systematic.

| Search region | \( N_t \) | \( N_b \) | \( m_{T2} \) [GeV] | \( p_{T2}^{\text{miss}} \) [GeV] | Data | Predicted background |
|---------------|--------|--------|----------------|----------------|------|-------------------|
| 22            | 1      | 2      | 200–350        | 250–400        | 596  | 580 ± 20 ± 60    |
| 23            | 1      | 2      | 200–350        | 400–500        | 59   | \( 41^{+6}_{-5} \) |

\textsuperscript{a}Deceased.
\textsuperscript{b}Also at Vienna University of Technology, Vienna, Austria.
\textsuperscript{c}Also at IRFU, CEA, Université Paris-Saclay, Gif-sur-Yvette, France.
\textsuperscript{d}Also at Universidade Estadual de Campinas, Campinas, Brazil.
\textsuperscript{e}Also at Universidade Federal de Pelotas, Pelotas, Brazil.
\textsuperscript{f}Also at Université Libre de Bruxelles, Bruxelles, Belgium.
\textsuperscript{g}Also at Institute for Theoretical and Experimental Physics, Moscow, Russia.
\textsuperscript{h}Also at Joint Institute for Nuclear Research, Dubna, Russia.
\textsuperscript{i}Also at Suez University, Suez, Egypt.
\textsuperscript{j}Also at British University in Egypt, Cairo, Egypt.
\textsuperscript{k}Also at Helwan University, Cairo, Egypt.
\textsuperscript{l}Also at Université de Haute Alsace, Mulhouse, France.
\textsuperscript{m}Also at Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia.
\textsuperscript{n}Also at CERN, European Organization for Nuclear Research, Geneva, Switzerland.
\textsuperscript{o}Also at RWTH Aachen University, III. Physikalisches Institut A, Aachen, Germany.
\textsuperscript{p}Also at University of Hamburg, Hamburg, Germany.
\textsuperscript{q}Also at Brandenburg University of Technology, Cottbus, Germany.
\textsuperscript{r}Also at MTA-ELTE Lendület CMS Particle and Nuclear Physics Group, Eötvös Loránd University, Budapest, Hungary.
\textsuperscript{s}Also at Institute of Nuclear Research ATOMKI, Debrecen, Hungary.
\textsuperscript{t}Also at Institute of Physics, University of Debrecen, Debrecen, Hungary.
\textsuperscript{u}Also at IIT Bhubaneswar, Bhubaneswar, India.
\textsuperscript{v}Also at Institute of Physics, Bhubaneswar, India.
\textsuperscript{w}Also at University of Visva-Bharati, Santiniketan, India.
\textsuperscript{x}Also at University of Ruhuna, Matara, Sri Lanka.
\textsuperscript{y}Also at Isfahan University of Technology, Isfahan, Iran.
\textsuperscript{z}Also at Yazd University, Yazd, Iran.
