Short title: Cerebrospinal fluid cytotoxicity in ALS/MND

Abstract

Various studies have suggested that a neurotoxic cerebrospinal fluid (CSF) profile could be implicated in amyotrophic lateral sclerosis (ALS). Here, we systematically review the evidence for CSF cytotoxicity in ALS and explore its clinical correlates. We searched the following databases with no restrictions on publication date: PubMed, Embase and Web of Science. All studies that investigated cytotoxicity in vitro following exposure to CSF from ALS patients were considered for inclusion. Meta-analysis could not be performed, and findings were instead narratively summarised. 28 studies were included in our analysis. Both participant characteristics and study conditions including CSF concentration, exposure time and culture model varied considerably across studies. Of 22 studies assessing cell viability relative to controls, 19 studies reported a significant decrease following exposure to ALS-CSF, while three early studies failed to observe any difference. Seven of eight studies evaluating apoptosis observed significant increases in the levels of apoptotic markers following exposure to ALS-CSF, with the remaining study reporting a qualitative difference. Although five studies investigated the possible relationship between CSF cytotoxicity and patient characteristics, such as age, gender and disease duration, none demonstrated an association with any of the factors. In conclusion, our analysis suggests that CSF cytotoxicity is a feature of sporadic and possibly also of familial forms of ALS. Further research is, however, required to better characterise its underlying mechanisms and to establish its possible contribution to ALS pathophysiology.

Introduction

Amyotrophic lateral sclerosis (ALS) is a relentlessly progressive, fatal neurodegenerative condition, characterised by the loss of motor neurons both in the brain and spinal cord, leading to paralysis. Sporadic ALS accounts for the majority of cases (about 90%), while the remaining occurrences, in which the disease is inherited, are known as familial ALS (Brown and Al-Chalabi, 2017). ALS is associated with several genes, for example, C9ORF72, TARDBP, SOD1 and FUS, with some genes also contributing to the presence of frontotemporal dementia (FTD).

Advances made in the last decade have led to a much improved understanding of ALS pathophysiology, with various mechanisms apparently involved (Hardiman et al., 2017). These include glutamate excitotoxicity, abnormal RNA metabolism, oxidative stress and mitochondrial dysfunction, amongst others. Given the involvement of impaired protein homeostasis, ALS, similar to other neurodegenerative diseases like Alzheimer’s disease, Parkinson’s disease and Huntington’s disease, is viewed as a proteinopathy, with most cases characterised pathologically by the presence of TDP-43-containing ubiquinated inclusions (Neumann et al., 2006). One longstanding question, however, pertains to the extent to which each of the above processes contributes to the overall pathophysiology.

Amongst the many lines of enquiry aiming to address this question, several studies have suggested that a neurotoxic cerebrospinal fluid (CSF) profile could be implicated in the disease process (Shaw, 2002; Matias-Guiu et al., 2010; Sumitha et al., 2019; Tokuda et al., 2019). CSF from ALS patients has in fact been shown to exert cytotoxicity in vitro (Tikka et al., 2002; Vijayalakshmi et al., 2009; Barber et al., 2011; Sumitha et al., 2019), and to provoke wide-ranging pathology, from neurofilament phosphorylation to musculoskeletal changes, when administered in vivo (Shahani et al., 2004; Gomez-Pinedo et al., 2018; Shanmukha et al., 2018). While the cause of these findings remains unclear, they nevertheless suggest the presence of one or more potentially toxic factors in ALS-CSF, with possible involvement in disease spread (Smith et al., 2015). Consistent with this possibility, recent in vivo evidence also includes pathological changes being observed distant to the CSF infusion site (Gomez-Pinedo et al., 2018).

A growing body of literature, including various proteomic studies, has helped to demonstrate that CSF composition in ALS may be abnormal (Barschke et al., 2017; Blasco et al., 2017; Hayashi et al., 2019). This includes findings of raised TDP-43 and neurofilament levels, as well as an altered inflammatory profile (Majumder et al., 2018; Schreiber et al., 2018; Gille et al., 2019). Thus, establishing the neurotoxicity of ALS-CSF and its possible determinants could open potential avenues for elucidating the pathophysiology of ALS. We therefore performed a systematic review of in vitro studies in order to review the evidence for CSF cytotoxicity in ALS and also to explore the possible association between cytotoxicity and clinical factors, such as patient age and disease duration.
Materials and methods

This study has been performed according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines (Moher et al., 2009).

Search strategy

The following databases were searched on 17 April 2020 to identify relevant studies: PubMed, Embase and Web of Science. No restrictions on publication date were applied. Search terms were as follows:

**PubMed**

(‘amyotrophic lateral sclerosis’ OR ‘ALS’ OR ‘motor neuron’ OR ‘motor neurone’ OR ‘MND’) AND (‘cerebrospinal fluid’ OR ‘CSF’)

**Embase**

(‘amyotrophic lateral sclerosis’ OR ‘ALS’ OR ‘motor neuron’ OR ‘motor neurone’ OR ‘MND’) AND (‘cerebrospinal fluid’ OR ‘CSF’)

**Web of Science**

(‘amyotrophic lateral sclerosis’ OR ‘ALS’ OR ‘motor neuron’ OR ‘motor neurone’ OR ‘MND’) AND (‘cerebrospinal fluid’ OR ‘CSF’)

We also reviewed the reference lists of all eligible studies and screened relevant reviews for potential citations. We collated all the references obtained from these searches and imported them into Endnote X9 for de-duplication.

Study selection

All studies that investigated cytotoxicity *in vitro* following exposure to CSF from ALS/MND patients were considered for inclusion. Any assay measuring cytotoxicity, cell viability, apoptosis or cell proliferation/cell cycle arrest was accepted. No restrictions on cell line were applied. Studies only investigating morphological and electrophysiological changes or changes in protein expression levels were excluded. *In vivo* and clinical studies were also excluded.

Only studies published in a peer-reviewed journal for which full-text articles are available in the English language were eligible. Reviews, case reports and conference abstracts were not considered for inclusion. Letters to the editor were, however, deemed eligible if sufficient information was provided. One author (KCNKK) screened the title and abstract of each paper. For studies meeting the inclusion criteria, full-text articles were retrieved and two authors (KCNKK and ARM) independently checked the studies for eligibility.

Data extraction

The primary outcome for this study was *in vitro* cytotoxicity, while secondary outcomes included the clinical correlates of CSF cytotoxicity, namely, the relationship between CSF cytotoxicity and patient characteristics including age, gender, disease duration, disease severity, survival time and site of onset. Data on these were independently extracted from studies by two authors (KCNKK and ARM).
One author (KCNKK) extracted data pertaining to study characteristics, which included the following: author, year of publication, country, participant characteristics of both ALS subjects and control subjects (including sample size, type of disease, age, gender, disease duration, survival time and site of onset), culture model, CSF concentration (v/v%), CSF diluent and presence of serum, exposure time, study groups, outcomes assessed, assays for outcome assessment and results.

Quality assessment

Given that no established guidelines currently exist for assessing the quality of in vitro studies, we generated a checklist based on modified Collaborative Approach to Meta-Analysis and Review of Animal Data from Experimental Studies (CAMARADES) criteria (Macleod et al., 2004; Mehta et al., 2019), with additional criteria drawn from the Biospecimen Reporting for Improved Study Quality (BRISQ) tool (Moore et al., 2011). Each study was assigned an overall quality score (total possible score = 9), with one point being given for each of the following: peer-reviewed publication, appropriate study approval stated, appropriate control group identified, procurement and maintenance of in vitro model described, appropriate description of CSF preservation process, storage temperature of CSF provided, blinded assessment of outcome stated, number of replicates performed stated and statement of potential conflict of interests.

Data synthesis

Appropriate summary statistics, including mean difference (MD), standardised mean difference (SMD), odds ratio and risk ratio could not be calculated from the extracted data, due to outcome measures (such as cell count) not commonly being reported by included studies, as well as heterogeneity being observed with respect to the interpretation of results. Thus, although a meta-analysis was initially planned as part of our analysis, we decided to summarise our results narratively. We first tabulated and described study characteristics for all studies, before summarising effectiveness results for the different outcomes including cytotoxicity/cell viability and apoptosis. P-values were calculated where it was possible to confidently do so. The clinical correlates of CSF cytotoxicity were also described narratively.

Data availability statement

All data have been published in this manuscript.
Results

We identified a total of 7378 records through database searching which, after de-duplication, reduced to 5567 results (Figure 1). After screening of title and abstract, 61 articles remained, of which 33 were conference abstracts, in vivo studies or did not report our outcomes of interest, and were therefore excluded. Thus, our analysis included 28 studies, conducted across various countries, such as USA, France, Japan, India and Spain (Table 1 shows the study characteristics of included studies).

Subject characteristics

The sample size of ALS subjects ranged from 3 to 31, with different ALS patient populations being studied, some of which include sporadic ALS, familial ALS, as well as patients with both ALS and FTD. Different criteria were also applied to ALS patient selection, since some studies included both subjects diagnosed with ‘probable’ and ‘definite’ ALS, while other studies limited participants to those with ‘definite’ ALS (see Supplementary Table 1 for additional information on participant characteristics including: disease description, age, gender, disease duration, survival time and site of onset). Control groups varied across studies, and, where possible, we broadly classified them into categories, such as ‘neurological control’, ‘neurodegenerative control’, ‘non-neurological control’ and ‘non-neurodegenerative control’. Due to ethical implications, control groups generally did not involve healthy individuals. Four studies did not include a control group.

Reporting of subject characteristics, including age, gender, disease duration, survival time and site of onset was inconsistent across studies, with the data less likely to be available for earlier studies. In studies that reported these, subjects were generally aged between around 45 and 75 years old, while gender ratio varied considerably from study to study. The clinical course was either described by disease duration or by survival time, although survival times were sometimes inexact in cases where some patients were still alive. A number of studies further reported the site of onset, namely, whether the disease was limb onset or bulbar onset. Other features that varied across studies include whether the subjects were drug-naïve at the time of lumbar puncture and whether age- and gender-matching were possible.

Study conditions

Heterogeneity was also observed with regard to study conditions. Different CSF concentrations ranging from 1% to 75% were used to assess cytotoxicity, while CSF exposure time also varied from 24 hours to 21 days. The most common CSF concentration and exposure times, however, were 10% and 24 hours or 48 hours, respectively. CSF was diluted in culture media such as DMEM in all but two studies, where the diluents were HBSS (Terro et al., 1996) and Locke’s solution (Fiszman et al., 2010). Serum was present in 17 studies, while eight studies observed serum-free conditions. The presence of serum could not be ascertained in the remaining three studies. In vitro culture models included spinal cord cultures, cortical neuron cultures and motor neuron cultures, as well as cell lines, such as NSC-34 (mouse spinal cord-neuroblastoma hybrid cell line), VSC 4.1 (cholinergic cAMP-differentiated motor neuron-neuroblastoma hybrid cell line) and U251 cell line (human glioma cell line). One recent study also assessed cytotoxicity in motor neurons differentiated from human embryonic stem cells (hESC) (Sumitha et al., 2019).
Quality assessment

Overall quality score of individual studies ranged from 4 to 8, with lower quality scores generally being observed in earlier studies (Supplementary Table 2). Most studies (24 out of 28) included one or more control groups. Procurement and maintenance of the in vitro model, as well as CSF preservation and storage temperature, were also usually described. Blinded outcome assessment was, however, rarely carried out, with only six studies stating that outcomes were blindly assessed.

Cytotoxicity/Cell viability

24 studies assessed cytotoxicity/cell viability through various techniques, including cell counting, trypan blue exclusion, MTS assay, MTT assay and LDH assay (Table 2). 19 studies observed a significant difference in cell viability following exposure to ALS-CSF compared to controls. The significance level across studies varied from \( p<0.05 \) to \( p<0.001 \), with the \( p \)-value not being specified in two studies. In one of these studies, however, the difference was only significant at 50% CSF concentration, but not at a concentration of 20% (Barber et al., 2011). Another study also failed to observe a decrease in neuronal survival at a 24-hour time point, but only reported the difference as significant on day 10 (Silani et al., 1987). Three early studies did not find any significant difference in cytotoxicity following exposure to ALS-CSF compared to controls (Askanas et al., 1981; Swift et al., 1988; Iwasaki et al., 1995). Two studies also assessed cytotoxicity within ALS patient populations. In the first study, which evaluated CSF cytotoxicity in 31 patients with ‘probable’ or ‘definite’ ALS at the time of diagnosis, 67.7% of patients were considered to possess cytotoxic CSF, with cytotoxicity being defined as a reduction in cell survival greater or equal to 25% compared to control (Galan et al., 2017). The second study compared CSF cytotoxicity between sporadic ALS patients with a high concentration of 4-hydroxynonenal (HNE) with those with a low concentration of HNE, and reported a significant difference both at 1% and 10% CSF concentration (Smith et al., 1998).

Apoptosis

Apoptosis was investigated by eight studies via techniques such as TUNEL assay, caspase-3 assay, caspase-9 assay, Bcl-2 assay and Bax assay. Seven of these studies were quantitative in nature and observed significant increases in the levels of different apoptotic markers, including caspase-3 and caspase-9, following exposure to ALS-CSF compared to controls. However, the increase in Bcl-2 levels following ALS-CSF exposure did not reach statistical significance (Ding et al., 2015; Sumitha et al., 2019). The remaining study, which only qualitatively evaluated apoptosis, reported the presence of TUNEL-stained nuclei in cells exposed to ALS-CSF, but not in those from control groups (Vijayalakshmi et al., 2011). We also note that ALS-FTD-CSF produced a significant increase in caspase-3 expression compared to ALS-CSF, although it was found to result in a significant decrease in Bcl-2 levels (Ding et al., 2015).

Clinical correlates

Five studies further assessed the possible relationship between CSF cytotoxicity and patient characteristics, including age, disease duration, disease severity, survival time and site of onset (Table 3). However, none of the studies demonstrated an obvious association between CSF cytotoxicity and any of the listed factors. Although one study reported differences based on age, gender and site of
onset, the difference was not statistically significant (Yanez et al., 2011). Another study also reported very low apoptotic activity in patients with the longest survival times, but a clear correlation was again not established (Barber et al., 2011).
Discussion

Our summary of findings in this study suggests that CSF cytotoxicity is a feature of sporadic and also possibly of familial ALS, with ALS-CSF appearing to exert cytotoxicity at a wide range of concentrations and exposure times, as well as across different culture models. Although a few studies failed to observe cytotoxicity following exposure to ALS-CSF compared to controls, we note that these were generally earlier studies (Askanas et al., 1981; Silani et al., 1987; Swift et al., 1988; Iwasaki et al., 1995). Our results also indicate an apoptotic component to ALS-CSF, with greater apoptosis being observed in cells following exposure to CSF from patients with both ALS and FTD (Ding et al., 2015). However, we fail to demonstrate a connection between CSF cytotoxicity and patient characteristics, such as age, gender, disease duration and survival time. The cause of this lack of association remains unclear, but suggests that CSF cytotoxicity may not be appropriate as a biomarker in ALS.

While the findings from this study support the cytotoxicity of ALS-CSF, little consensus exists as to the factors underlying it. Different potential candidates have been suggested to explain ALS-CSF cytotoxicity, with glutamate being an important example, given the potentially raised glutamate levels in ALS patients (Spreux-Varoquaux et al., 2002; Fiszman et al., 2010). However, although glutamate antagonists have been shown to have a protective effect on CSF neurotoxicity, less evidence is available to support the toxicity of glutamate endogenous to ALS-CSF (Couratier et al., 1994; Tikka et al., 2002; Anneser et al., 2006; Matias-Guiu et al., 2010). Riluzole, despite its modest clinical benefit, also failed to confer neuroprotection in vitro (Yanez et al., 2011).

Another potential mechanism underlying CSF-induced neurodegeneration, given the increasing recognition of ALS as a proteinopathy and the growing evidence supporting the prion-like properties of several key ALS proteins, notably that of TDP-43 and SOD1 (Brauer et al., 2018), is proteostasis. This is supported by findings demonstrating that CSF containing misfolded SOD1 could trigger neurodegeneration in NSC-34 cells (Tokuda et al., 2019). Another recent study further revealed that ALS-CSF could promote TDP-43 proteinopathy both following in vitro exposure and in vivo injection, although the observed changes were much more pronounced in hTDP43 transgenic mice, than in normal mice (Mishra et al., 2020). Other ALS proteins that have been suggested to possess prion-like properties include FUS and C9ORF72-associated dipeptide repeat proteins (Nomura et al., 2014; Westergard et al., 2016), but whether they could exert toxicity at levels comparable to that of ALS-CSF is unclear.

Consistent with the non-cell autonomous component of ALS pathophysiology (Zhao et al., 2019), ALS-CSF toxicity was also found to extend to glial cells. Notably, exposure to ALS-CSF has been found to result in pro-inflammatory activity, both in astrocytes and microglia (Mishra et al., 2016; Mishra et al., 2017). Furthermore, ALS-CSF was also found to produce different changes in motor neurons co-cultured with glia than in motor neuron mono-cultures (Barber et al., 2011), although the reasons for this disparity remain to be established. Highlighting the potentially inflammatory aspect of ALS-CSF, a number of immune components and growth factors have also been linked to CSF cytotoxicity (Matias-Guiu et al., 2010).

Acknowledging that the pathophysiology of ALS remains unknown, characterising cytotoxicity associated with ALS-CSF could greatly improve our understanding of the mechanisms responsible for neurodegeneration in ALS patients. These insights could arise from additional studies employing a proteomic approach, given that few such studies have been performed so far (Varghese et al., 2013). In vitro results also need to be complemented by in vivo evidence, which have to date revealed various changes following CSF infusion, including neurofilament phosphorylation, endoplasmic reticulum stress, as well as motor dysfunction (Deepa et al., 2011; Vijayalakshmi et al., 2011; Shanmukha et al.,...
Although the observed changes have been reported to be histologically similar to sporadic ALS cases (Gomez-Pinedo et al., 2018), whether CSF toxicity studies accurately capture the mechanisms involved in ALS pathophysiology, and could serve as an important model for ALS, is not yet clear. Various lines of evidence, however, hint at a potential contribution of CSF in the spread of the disease in ALS patients, with one major appeal for this model being its explanatory potential with respect to clinical observations (Smith et al., 2015).

Indeed, despite numerous models having been posited to explain disease evolution in the context of ALS, clinical observations remain incompletely explained. In addition to being highly heterogeneous, the disease is occasionally found to spread in a non-contiguous manner, with the onset believed to be multifocal in nature (Sekiguchi et al., 2014). Trans-synaptic spread and cell-to-cell transmission via exosomes have both been suggested as possible mechanisms of spread (Braak et al., 2013; Iguchi et al., 2016). With the evidence for exosome transmission still a topic of debate (Brauer et al., 2018), future research aimed at uncovering its possible contribution could play an important role in determining the importance of CSF circulation as a route of spread. Necroptosis, in which the contents of the dying cell are released into the surrounding environment, is another possible mechanism that may deserve investigation (Ito et al., 2016).

Intriguingly, while considerably more literature surrounds CSF cytotoxicity in the context of ALS, this does not appear to be a feature specific to ALS. Similar to ALS, the neurotoxicity of CSF from patients with Parkinson’s disease patients has been demonstrated as early as 1999, with degeneration of dopaminergic neurons being observed in vitro (Le et al., 1999). This finding has also been confirmed more recently by a different group (Kong et al., 2015). Furthermore, we also found that, in some of the studies included in this review, CSF from control groups could also exert cytotoxicity. For instance, one study, in which ALS-CSF cytotoxicity was assessed alongside CSF from ten control subjects undergoing lumbar puncture to exclude subarachnoid haemorrhage or viral meningitis, demonstrated significantly increased cytotoxicity following exposure to CSF from control subjects compared with ALS-CSF (Barber et al., 2011).

Nevertheless, although we consider our findings to be suggestive of the cytotoxicity of ALS-CSF, we acknowledge a number of limitations in this review. First, included studies assessed cytotoxicity in different cell lines, some of which, including the VSC4.1 and U251 cell lines, could potentially have responded differently to CSF exposure compared to motor neurons. The NSC-34 cell line, which has been used by many studies to study CSF cytotoxicity has also been subject to controversy in the past (Hornburg et al., 2014). Given the qualitative nature of this study, it was not possible to investigate the difference in vulnerability between cortical and spinal neurons to CSF cytotoxicity. The variety of cell lines employed, some of which could differ considerably from human motor neurons in their response to CSF exposure, is also a major limitation of our study. Notwithstanding this, one recent study that post-dates our literature search, in which human iPSC-derived spinal motor neurons were exposed to ALS-CSF, supports the cytotoxicity of ALS-CSF towards motor neurons (Brauer et al., 2020).

Second, the considerable heterogeneity with regard to reporting of study results and their interpretation meant that we were unable to conduct a meta-analysis. Reporting of study characteristics and participant details was also variable, and we therefore failed to further analyse the association between patient characteristics and CSF cytotoxicity. Notably, other features of ALS, including C9ORF72 status and the presence of cognitive or behaviour change were not commonly assessed in study populations, and could therefore be considered in future studies. The time point at which lumbar puncture was performed, namely, whether it was part of diagnostic work-up earlier in disease trajectory, or later in disease course, was also not always stated. Finally, the contribution of study conditions, including CSF concentration and exposure time, could also be more extensively
investigated. Although the CSF diluent and the presence of serum did not appear to influence CSF cytotoxicity overall, a definite conclusion cannot be drawn.

Moving forwards, we believe that there is a need for future studies assessing CSF cytotoxicity to provide an accurate record of study procedures and ensure greater consistency in reporting of study results, in order to facilitate meta-analysis of research findings. We thus present a checklist (Supplementary Table 3), which, though not intended as a comprehensive guideline, includes items of possible relevance to the assessment of CSF cytotoxicity. Disease staging, for instance, despite its known association with CSF composition, is not always reported by studies. In particular, we recommend that, with respect to study results, steps involved in the calculation of the summary statistic, as well as the study groups involved, are clearly described, with the raw data made available for possible future analyses.
Conclusion

The lack of success in finding a possible treatment for ALS, with the only globally licenced drug for ALS so far being riluzole (Bensimon et al., 1994), has led to various lines of enquiry aimed at identifying the processes underlying ALS pathophysiology. Here, we performed a qualitative assessment of the existing literature, the outcome of which suggests that CSF cytotoxicity, a feature which has previously been linked to ALS pathophysiology, can be observed in sporadic and possibly also in familial forms of ALS. Thus, improving our understanding of the mechanisms responsible for CSF cytotoxicity, and, importantly, establishing their possible contribution in ALS pathophysiology, could play a potential role in future ALS research.

Figure legends

**Figure 1: PRISMA flow diagram.** PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram describing each stage of the study selection process. *Quantitative analysis could not be performed due to outcome measures required to calculate appropriate summary statistics not commonly being reported by included studies. Results were also interpreted differently across studies, and thus could not be pooled together.*
Table 1. Study characteristics of included studies

| Author/s (Year of publication) | Country | ALS patient population | Control subjects | Study groups | CSF concentration (v/v%) | CSF diluent* | Exposure time | Culture model | Quality score |
|-------------------------------|---------|------------------------|------------------|--------------|-------------------------|-------------|--------------|---------------|---------------|
| Askanas et al. (1981)         | USA     | 10 patients with ALS   | 7 neuromuscular control patients (NC) 2 non-neuromuscular control patients (NNC) | - Cells exposed to ALS-CSF - Cells exposed to NC-CSF - Cells exposed to NNC-CSF - Untreated cells | 50%, 75% | Culture medium | 8 days | Rat spinal cord culture | 4 |
| Silani et al. (1987)          | Italy   | 3 patients with sporadic ALS | 4 control patients (Con) | - Cells exposed to ALS-CSF - Cells exposed to Con-CSF - Untreated cells | 10% | DMEM (+) | 24 hours | Human fetal motor cortex culture | 5 |
| Swift et al. (1988)           | USA     | 4 patients with ALS    | None             | - Cells exposed to ALS-CSF - Untreated cells | 1.25%, 2.5%, 5%, 10%, 37.5% | Culture medium | 21 days | Rat spinal motor neuron culture | 4 |
| Couratier et al. (1993)       | France  | 10 patients with ALS   | 10 neurodegenerative control patients (NC) 10 non-neurodegenerative control patients (NNC) | - Cells exposed to ALS-CSF - Cells exposed to NC-CSF - Cells exposed to NNC-CSF - Untreated cells | 10%, 20%, 50% | MEM Earle’s salts (+) | 24 hours | Rat cortical neuron culture | 5 |
| Couratier et al. (1994)       | France  | 8 patients with ALS    | 8 non-neurodegenerative control patients (NNC) | - Cells exposed to ALS-CSF - Cells exposed to NNC-CSF - Untreated cells | 50% | MEM Earle’s salts (+) | 24 hours | Rat cortical neuron culture | 5 |
| Iwasaki et al. (1995)         | Japan   | 10 patients with ALS   | 10 neurodegenerative control patients (NC) 10 non-neurodegenerative control patients (NNC) | - Cells exposed to ALS-CSF - Cells exposed to NC-CSF - Cells exposed to NNC-CSF - Untreated cells | 10%, 25%, 50% | DMEM (+) | 8 days | Rat spinal cord culture | 5 |
| Terro et al. (1996)           | France  | 7 patients with ALS    | 7 non-neurodegenerative control patients (NNC) | - Cells exposed to ALS-CSF - Cells exposed to NNC-CSF - Untreated cells | 20% | HBSS (+) | 48 hours | Rat cortical neuron culture | 5 |
| Smith et al. (1998)           | USA     | 13 sporadic ALS patients with high CSF HNE levels 14 sporadic ALS patients with low CSF HNE levels | None             | - Cells exposed to high HNE ALS-CSF - Cells exposed to low HNE ALS-CSF | 1%, 10% | Culture medium | 48 hours | VSC 4.1 cell line | 7 |
| Tikka et al. (2002)           | Finland | 5 ALS patients homozygous for the D90A CuZn-SOD mutation 5 patients with familial ALS 16 patients with sporadic ALS | 24 neurological control patients (NC) | - Cells exposed to D90A ALS-CSF - Cells exposed to fALS-CSF - Cells exposed to sALS-CSF - Cells exposed to NC-CSF - Untreated cells | 25% | DMEM (+) | 24 hours | Rat spinal cord culture | 8 |
| Sen et al. (2005)             | India   | 10 patients with ALS   | 10 neurological control patients (NC) | - Cells exposed to ALS-CSF - Cells exposed to NC-CSF - Untreated cells | 10% | Eagle’s MEM (+) | 24 hours | Rat spinal cord culture | 7 |

*Serum presence and serum-free conditions are indicated in brackets as ‘+’ and ‘-’ respectively.

DMEM: Dulbecco's Modified Eagle Medium
HBSS: Hank's Balanced Salt Solution
hESC: human embryonic stem cell
HNE: 4-hydroxynonenal
MEM: Minimal Essential Medium
NSC-34: mouse spinal cord-neuroblastoma hybrid cell line
U251: human glioma cell line
VSC 4.1: cholinergic cAMP-differentiated motor neuron-neuroblastoma hybrid cell line
## Table 2. Summary of findings of included studies

| Author/s (Year of publication) | Outcome/s assessed | Assay/s for assessing outcome | Results |
|-------------------------------|-------------------|-------------------------------|---------|
| Askanas *et al.* (1981)       | Cell viability    | NSE radioimmunoassay          | Little evidence for toxic effect of CSF suggested by slight decrease (~9%) in enolase activity of CSF-treated cultures (ALS and disease controls) compared with untreated cultures. |
| Silani *et al.* (1987)        | Cell viability    | NS                            | No obvious decrease in neuronal survival following exposure to ALS-CSF at 24h. Neuronal cell loss only observed at day 5, with the decrease becoming significant at day 10. |
| Swift *et al.* (1988)         | Cell viability    | NS                            | No change in motor neuron survival observed following exposure by ALS-CSF. |
| Couratier *et al.* (1993)     | Cell viability    | Cell counting                 | Significant decrease in neuronal survival following exposure to 50% ALS-CSF compared to controls (p<0.001). A smaller decrease in survival was observed at more dilute ALS-CSF concentrations (20% and 10%). |
| Couratier *et al.* (1994)     | Cell viability    | Cell counting, FDA staining   | Significant decrease in neuronal survival following exposure to ALS-CSF compared to controls (p<0.001). |
| Iwasaki *et al.* (1995)       | Cell viability    | Cell counting                 | No significant differences in neuronal survival following exposure to ALS-CSF compared to controls at any CSF concentration. |
| Terro *et al.* (1996)         | Cell viability    | Cell counting, FDA and PI double staining | Significant decrease in neuronal survival following exposure to ALS-CSF compared to controls (p<0.001). |
| Smith *et al.* (1998)         | Cell viability    | Trypan blue staining, MTS assay | Significant difference in VSC 4.1 cell survival between samples exposed to high HNE ALS-CSF and low HNE ALS-CSF both at 1% CSF and 10% CSF (p<0.001). |
| Tikka *et al.* (2002)         | Cell viability, apoptosis | Cell counting, bis-benzimide staining | Significant increase in the proportion of apoptotic neurons and significant decrease in the percentage of surviving neurons following exposure to D90A ALS-CSF, fALS-CSF and sALS-CSF compared to controls (p<0.05). |
| Sen *et al.* (2005)           | Cell viability    | Live/dead cell assay (calcein-AM and ethidium homodimer) | Significant decrease in both motor neuron survival and survival of other spinal neurons following exposure to ALS–CSF compared to controls (p<0.001). Significant difference between motor neuron survival compared to survival of other spinal neurons also observed (p<0.001). |
| Anneser *et al.* (2006)       | Cell viability, apoptosis | Cell counting, trypan blue staining, PI/DAPI staining, TUNEL assay | Significant increase in apoptotic cells and significant decrease in motor neuron survival following exposure to ALS-CSF compared to controls (p<0.001). Significant decrease in survival also observed in mixed spinal cord culture following exposure to ALS-CSF (p-value not specified). |
| Shobha *et al.* (2007)        | Cell viability    | LDH assay                     | Increased LDH activity following exposure to ALS-CSF compared to controls (p-value not specified). |
| Vijayalakshmi *et al.* (2009) | Cell viability    | MTT assay, LDH assay          | Significant reduction in viability of NSC-34 cells (p<0.001) and significant increase in LDH activity (p<0.01) following exposure to ALS-CSF compared to controls. |
| Fiszman *et al.* (2010)       | Cell viability    | Cell counting, trypan blue staining | Significant decrease in neuronal survival following exposure to ALS-CSF compared to controls (p<0.05). |
| Barber *et al.* (2011)        | Cell viability    | Cell counting                 | Significant decrease in motor neuron survival following exposure to 50% ALS-CSF (p<0.05) and 50% Con-CSF (p<0.005) compared to untreated samples. Decrease in motor neuron survival however not significant at 20% ALS-CSF and 20% Con-CSF. |
| Authors            | Type          | Assay(s)               | Findings                                                                 |
|--------------------|---------------|------------------------|--------------------------------------------------------------------------|
| Kulshreshtha et al. (2011) | Cell viability | LDH assay             | Significant increase in LDH activity following exposure to ALS-CSF compared to controls (p<0.01). |
| Vijayalakshmi et al. (2011) | Apoptosis     | TUNEL assay            | Significant decrease in LDH activity following exposure to ALS-CSF compared to controls. |
| Yanez et al. (2011) | Cell viability | MTT assay, LDH assay   | Significant decrease in neuronal viability (p<0.001) and significant increase in LDH activity (p<0.05) following exposure to ALS-CSF compared to controls. |
| Varghese et al. (2013) | Cell viability | MTT assay, LDH assay   | Significant decrease in cell viability and significant increase in LDH activity following exposure to ALS-CSF compared to controls (p<0.001). |
| Gomez-Pinedo et al. (2014) | Apoptosis     | Caspase-3 assay        | Significant increase in caspase-3 positive cells following exposure to ALS-CSF compared to controls (p<0.05). |
| Yanez et al. (2014) | Cell viability | MTT assay              | Significant decrease in neuronal viability following exposure to ALS-CSF compared to control (p<0.05). |
| Ding et al. (2015)  | Apoptosis     | Caspase-3 assay, Bcl-2 assay | Significant increase in cleaved caspase-3 levels following exposure to ALS-CSF (p<0.05) and ALS-FTD-CSF (p<0.01) compared to control. Significant decrease in Bcl-2 levels following exposure to ALS-FTD-CSF compared to both ALS-CSF and control (p<0.05). |
| Sharma et al. (2015) | Cell viability | MTT assay              | Significant decrease in neuronal viability following exposure to ALS-CSF compared to controls (p<0.001). |
| Vijayalakshmi et al. (2015) | Apoptosis     | TUNEL assay, caspase-3 assay | Significant increase in proportion of TUNEL-positive cells and expression of caspase-3 following exposure to ALS-CSF compared to controls (p<0.001). |
| Galan et al. (2017)  | Cell viability | MTT assay              | CSF cytotoxicity was observed in 21 patients (67.7%) while the remaining 10 patients (32.3%) were considered to possess non-cytotoxic CSF (Cytotoxicity was defined as a decrease in neuronal viability greater or equal to 25% compared to control) |
| Shruthi et al. (2017) | Cell viability, apoptosis | MTT assay, caspase-3 assay | Significant decrease in cell viability (p<0.05) and significant increase in caspase-3 expression (p<0.05) following exposure to ALS-CSF compared to controls. |
| Sumitha et al. (2019) | Cell viability, apoptosis | MTT assay, LDH assay, caspase-9 assay, Bcl-2 assay, Bax assay | Significant decrease in neuronal viability and significant increase in LDH activity following exposure to ALS-CSF compared to controls (p<0.001). Non-significant increase in proportion of BCL2-positive neurons but significant increases in proportion of Bax-positive and caspase-9-positive neurons (p<0.05) following exposure to ALS-CSF compared to controls. |
| Tokuda et al. (2019) | Cell viability | Cell Counting Kit-8    | Significant decrease in cell viability following exposure to ALS-CSF compared to controls (p<0.01) |

**Abbreviations:**
- DAPI: 4',6-diamidino-2-phenyindole, diacetate
- FDA: fluorescein diacetate
- LDH: lactate dehydrogenase
- MTT: 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide
- NS: not specified
- NSE: neuron-specific enolase
- PI: propidium iodide
- TUNEL: terminal deoxynucleotidyl transferase dUTP nick end labeling
| Author/s (Year of publication) | Patient characteristic | Results                                                                                                                                 |
|-------------------------------|------------------------|-------------------------------------------------------------------------------------------------------------------------------------------|
| Tikka et al. (2002)           | Survival time          | Little correlation observed between CSF cytotoxicity and patient survival time. Considerably lower apoptotic activity was however observed in the two patients with the longest survival times. |
| Anneser et al. (2006)         | Age, disease duration  | Little correlation observed between CSF cytotoxicity and age ($r = -0.22$) or disease duration prior to lumbar puncture ($r = -0.24$).        |
| Barber et al. (2011)          | Age, gender, disease duration | Little correlation observed between CSF cytotoxicity and age or disease duration. CSF cytotoxicity was also not influenced by gender.           |
| Yanez et al. (2011)           | Age, gender, disease duration, disease severity, site of onset | Although female patients, younger patients and patients with bulbar onset ALS appeared to possess more cytotoxic CSF, the differences did not reach statistical significance. No relationship was also observed between CSF cytotoxicity and disease duration or disease severity. |
| Galan et al. (2017)           | Age, gender, disease duration, survival time, site of onset | No significant differences were observed between patients with cytotoxic CSF and those with non-cytotoxic CSF with respect to age, gender, disease duration, survival time or site of onset. |
Figure 1: PRISMA flow diagram. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram describing each stage of the study selection process. *Quantitative analysis could not be performed due to outcome measures required to calculate appropriate summary statistics not commonly being reported by included studies. Results were also interpreted differently across studies, and thus could not be pooled together.

215x279mm (300 x 300 DPI)
Systematic review of *in vitro* evidence suggests that cerebrospinal fluid cytotoxicity is a feature of sporadic and possibly also of familial forms of amyotrophic lateral sclerosis. Further research is, however, required to elucidate the mechanisms underlying its toxicity, and to establish its possible contribution in overall pathophysiology.
