Abstract

We studied the production of neutron-rich nuclides in multinucleon transfer collisions of stable and radioactive beams in the mass range A\sim 40–60. We first presented our experimental cross section data of projectile fragments from the reaction of \textsuperscript{40}Ar (15 MeV/nucleon) with \textsuperscript{64}Ni, \textsuperscript{58}Ni and \textsuperscript{27}Al. We then compared them with calculations based on either the deep-inelastic transfer (DIT) model or the constrained molecular dynamics (CoMD) model, followed by the statistical multifragmentation model (SMM). An overall good agreement of the calculations with the experimental data is obtained. We continued with calculations of the reaction of \textsuperscript{40}Ar (15 MeV/nucleon) with \textsuperscript{238}U target and then with reactions of \textsuperscript{48}Ca (15 MeV/nucleon) with \textsuperscript{64}Ni and \textsuperscript{238}U targets. In these reactions, neutron-rich rare isotopes with large cross sections are produced. These nuclides, in turn, can be assumed to form radioactive beams and interact with a subsequent target (preferably \textsuperscript{238}U), leading to the production of extremely neutron-rich and even new isotopes (e.g. \textsuperscript{60}Ca) in this mass range. We conclude that multinucleon transfer reactions with stable or radioactive beams at the energy of around 15 MeV/nucleon offer an effective route to access extremely neutron-rich rare isotopes for nuclear structure or reaction studies.

1 Introduction

The study of the chart of the nuclides toward the astrophysical r-process path and the neutron drip-line continues to receive special attention by the nuclear physics community (see, e.g., [1234]). Moreover, the efficient production of very neutron-rich nuclides constitutes a central issue in current and upcoming rare isotope beam facilities (see, e.g., [5678910111213]).

Neutron-rich nuclides are routinely produced by spallation, fission or projectile fragmentation [14]. Spallation is a traditional mechanism to produce rare isotopes for ISOL-type techniques [15]. Projectile fission has proven very effective to produce light and heavy fission fragments (see, e.g., [161718]). Finally, projectile fragmentation has been established as a universal approach to produce exotic nuclei at beam energies typically above 100 MeV/nucleon (see, e.g., [192021222324]). We point out that in this approach, optimum neutron excess in the fragments is achieved by stripping the maximum possible number of protons (and a minimum number of neutrons).

To arrive at an even higher neutron-excess in the products, apart from proton stripping, capture of neutrons from the target is necessary. Such a possibility is offered by reactions involving nucleon exchange at beam energies from the Coulomb barrier [252627] to the Fermi energy (below 40 MeV/nucleon) [2829]. There is renewed interest in such reactions nowadays as evidenced by recent experimental (e.g. [3031323334]) and theoretical (e.g. [353637383940]) works. These efforts focus mainly on multinucleon transfer reactions near the Coulomb barrier. From a practical standpoint, in such reactions, the low velocities of the fragments and the wide angular and ionic charge state distributions may limit the collection efficiency for the most neutron-rich products.

The reactions in the Fermi energy regime (i.e. 15–35 MeV/nucleon) combine the advantages of both low-energy (i.e., near and above the Coulomb barrier) and high-energy (i.e., above 100 MeV/nucleon) reactions. At this energy, the overlap of the peripheries of the projectile and the target enhances the N/Z of the resulting fragments, while the velocities are high enough to allow efficient in-flight collection and separation.

Our previous experimental studies of projectile fragments from 15 and 25 MeV/nucleon reactions of $^{86}$Kr [2829111213] indicated substantial production of neutron-rich fragments. Our recent article [41] elaborates on our current understanding of the reaction mechanism and our ability to describe it quantitatively with the phenomenological DIT (deep inelastic transfer) model, as well as with the microscopic CoMD (Constrained Molecular Dynamics) model. As already pointed out in our previous works, our multinucleon transfer approach in the energy regime of 15–25 MeV/nucleon offers the possibility of essentially
adding neutrons (along with the usual stripping of protons) to a given stable (or radioactive) projectile via interaction with a neutron-rich target.

In this article, after a short overview of our previous experimental measurements with an $^{40}$Ar (15 MeV/nucleon) beam, we present systematic calculations of the production cross sections based on either the phenomenological DIT model or the microscopic CoMD model. The good description of the experimental results with both the microscopic CoMD code, as well as, with the phenomenological DIT code, suggest the possibility of using the present theoretical framework for the prediction of exotic nuclei employing radioactive beams that will soon be available in upcoming facilities. As examples, we present the production cross sections and the rates of neutron-rich nuclei using radioactive beams of $^{46}$Ar and $^{54}$Ca at 15 MeV/nucleon. The structure of the paper is as follows. In section 2, we give a short description of the experimental methods and in section 3 an overview of the models used. In sections 4–6 we compare our calculations to data for the stable beams $^{40}$Ar and $^{48}$Ca. Then, in sections 7 and 8 we present calculations with the radioactive beams $^{46}$Ar and $^{54}$Ca. Finally, we close with a discussion and summary.

2 Brief description of the experimental data and apparatus

Experimental data on neutron rich nuclide production with a beam of $^{40}$Ar (15 MeV/nucleon) were obtained at the Cyclotron Institute of Texas A&M University, in parallel to a series of measurements with a $^{86}$Kr (15 MeV/nucleon) beam already published in [43]. A preliminary version of the $^{40}$Ar data has already been presented in [45]. The experimental setup has been presented in detail in [43]. For completeness, we give a brief overview of the experimental methods here. A 15 MeV/nucleon $^{40}$Ar$^{9+}$ beam hit targets of $^{64}$Ni, $^{58}$Ni and $^{27}$Al with thickness of 2 mg/cm$^2$. Projectile fragments were collected and identified using the MARS recoil separator applying the techniques developed and documented in [43]. The $^{40}$Ar beam was send on the primary target location of MARS with an inclination of 4° with respect to the optical axis of the separator and projectile fragments were collected in the polar angular range of 2.2–5.5° (in a solid angle of $\Delta\Omega = 4.0$ msr). After interaction with the target, the fragments traversed a PPAC (parallel-plate avalanche counter) at the intermediate image location (for position and magnetic rigidity measurement and START-time information) and then they were focused at the end of the device passing through a second PPAC (for image size monitoring and STOP-time information). Finally the fragments were collected in a 5x5 cm$^2$ $\Delta$E–E Si detector telescope (with 60 and 1000 µm thickness, respectively). Following standard techniques of $B_{\rho}$–$\Delta$E–E–TOF (magnetic rigidity, energy-loss, residual energy and time-of-flight, respectively), the atomic number Z, the mass number A, the velocity and the ionic charge of the fragments were obtained
on an event-by-event basis. Data were obtained in a series of overlapping magnetic rigidity settings of the spectrometer in the range 1.1-1.5 Tm. We note that this magnetic rigidity range did not fully cover the neutron-deficient side of the product distributions which extends down to approximately 0.8 Tm according to our calculations with the models discussed in the following. (The neutron-deficient isotopes with incomplete Bρ coverage lie to the left of the thin solid lines in Figs. 1,2,3 and 6.)

In order to obtain total cross sections of the produced isotopes, we applied corrections to the measured yields for the limited angular coverage of the spectrometer, as performed in our previous work [43]. The corrections were based on simulations of the reactions using the DIT code (see below) followed by a deexcitation code [43]. We used the ratio of the filtered to unfiltered calculated yields to correct the measured yield data (obtained in the limited angular acceptance of the spectrometer) and to extract the total production cross section for each isotope that we present and discuss in the following.

In figure 1 we present the extracted cross sections of the isotopes of elements Z=19–12 for the three reactions studied: $^{40}$Ar (15 MeV/nucleon) + $^{64}$Ni, $^{58}$Ni and $^{27}$Al, represented by closed (black) circles, open (red) circles and open (blue) squares, respectively. We clearly observe enhanced production of neutron-rich isotopes with the more neutron-rich target of $^{64}$Ni (N/Z=1.28), followed by $^{58}$Ni (N/Z=1.07) and, finally, by $^{27}$Al (N/Z=1.08). Interestingly, few-neutron pickup nuclides are produced in all three reactions. These nuclides lie to the right of the vertical dotted lines in figure 1 (and subsequent figures). As expected, the reaction with the most neutron-rich of the three targets leads to the highest production of these nuclides in the data. Especially for elements very close to the projectile, e.g. Z=19–16, the neutron-pickup possibility provides a distinct advantage of these reactions in comparison to the well-established projectile fragmentation approach, in which the neutron pickup possibility is suppressed, as we will also discuss in the following.

3 Outline of the theoretical models

The calculations performed in this work are based on a two-stage Monte Carlo approach. The dynamical stage of the collision was described by two different models: First, we employed the phenomenological deep-inelastic transfer (DIT) model [46,47,48] simulating stochastic nucleon exchange in peripheral collisions. This model has been successful in describing the N/Z, excitation energy, and kinematical properties of excited quasiprojectiles in a number of recent studies (e.g. [49] and references therein), including our work on rare isotope production below the Fermi energy, as referenced in the previous section.
We also used the microscopic constrained molecular dynamics (CoMD) model \cite{50,51,52,53,54} successfully used in studies of low-energy reaction dynamics. This code follows the general approach of the quantum molecular dynamics (QMD) models \cite{55} and describes the nucleons as localized Gaussian wave packets. It implements an effective nucleon-nucleon interaction with a nuclear-matter compressibility of $K = 200$ (soft EOS) and several forms of the density dependence of the nucleon-nucleon symmetry potential. Moreover, it imposes a phase space constraint to restore the Pauli principle during the time evolution of the system. As in our recent studies at 15 and 25 MeV/nucleon \cite{44,56}, in this work we mainly employed a symmetry potential proportional to the density, (that we called the standard symmetry potential). We also performed calculations with a symmetry potential proportional to the square root of the density (soft symmetry potential), as well as with one proportional to the square of the density (hard symmetry potential). Both of them lead to nearly similar results for the peripheral collisions involved in this study and are not shown in the paper. In the present CoMD calculations, the dynamical evolution of the system was stopped at $t = 300$ fm/c ($10^{-21}$ s) \cite{44}.

After the dynamical stage simulated either by the DIT code or the CoMD code, the deexcitation stage of the reaction was described by the statistical code SMM (Statistical Multifragmentation Model) of Botvina \cite{57,58}. In this code, thermally equilibrated partitions of hot fragments are generated in a hot stage, which is followed by the propagation of the fragments in their mutual Coulomb field and their secondary deexcitation as they fly in their asymptotic directions. We note that for low excitation energy events ($E^* < 1$ MeV/nucleon) of relevance to the production of very neutron-rich nuclei, the SMM code describes adequately the deexcitation process as a cascade of emissions of neutrons and light charged particles using the Weisskopf-Ewing model of statistical evaporation \cite{47,48}.

After this brief outline the models, we wish to comment on the physical basis of the two models used to describe the dynamical stage. The DIT model is a phenomenological nucleon-exchange model with empirical parameters carefully chosen to describe peripheral reactions in the Fermi energy and below. On the other hand, the CoMD model is a fully microscopic (semiclassical) N-body model employing empirical interactions among the nucleons adjusted to describe the known static properties of nuclei (i.e., radii, masses, etc.). As such, the code has essentially no adjustable parameters that depend on the reaction dynamics. Moreover, the CoMD approach, contrary to mean-field models, naturally takes into account correlations among nucleons that are important to describe observables involving fluctuations, as for example the nucleon transfer in peripheral heavy-ion collisions.

We mention that multinucleon transfer in reactions near the Coulomb barrier has been described with some success by the fully quantal time-dependent
Hartree-Fock (TDHF) approach (see, e.g., Ref. [36,37] and references therein), which is, however, not appropriate for energies well above the Coulomb barrier. For the above reasons, we understand that the microscopic CoMD model offers a valuable theoretical microscopic framework for the description of the present reactions. Furthermore, the CoMD may be reliably applied to situations where no experimental data are available, especially in reactions with neutron-rich rare isotope beams.

4 Reactions with the ⁴⁰Ar projectile at 15 MeV/nucleon

In this section, we first present comparisons of the calculated production cross sections of ⁴⁰Ar projectile fragments with our experimental data. Since our goal is toward the optimum production of neutron-rich isotopes, the comparisons will focus on the reaction of ⁴⁰Ar with the ⁶⁴Ni target. Similar comparisons were performed with the other two targets (resulting in equivalent quality of agreement) and are not reported in this paper.

In figure 2, we show the calculated mass distributions of projectile fragments with Z=19–12 from the reaction ⁴⁰Ar (15 MeV/nucleon) + ⁶⁴Ni obtained by DIT/SMM [solid (red) line] and by CoMD/SMM [dotted (blue) line] and compare them with the experimental data (closed points) described above (figure 1). We observe that the results of the two models are almost identical and in good agreement with the experimental data, especially for isotopes close to the projectile (Z=19–16). As mentioned in section 2, the discrepancy between the calculation and the experimental data on the neutron-deficient side is due to incomplete coverage of the magnetic rigidity in the experiment that resulted in loss or incomplete collection of the neutron-deficient nuclides. Moreover, the agreement of the DIT calculations with those with the microscopic CoMD model, as well as with the data gives us confidence in the use of the DIT code for further systematic study of reactions for which no experimental data exist at present.

In figure 3, we proceed to show the DIT/SMM calculations for the reaction of ⁴⁰Ar (15 MeV/nucleon) with the heavy and very neutron-rich ²³⁸U (N/Z=1.59) target [dashed (blue) line] along with the DIT/SMM calculations [solid (red) line] of ⁴⁰Ar+⁶⁴Ni and the experimental data (closed points) that we already presented in figure 2. As we might expect, the heavy ²³⁸U target leads to further enhanced production of neutron-rich isotopes, especially at the tails of the distributions, as compared to those with the ⁶⁴Ni target. For further comparison in figure 3, we also show the projectile fragmentation data of Notani [61,62] for the reaction ⁴⁰Ar (94 MeV/nucleon) + ¹⁸¹Ta (open circles). In these data we observe the absence of neutron-pickup nuclides. However, such products are reported in the fragmentation data of Zhang et al. [63] with a
beam of $^{40}$Ar (57 MeV/nucleon) on $^{181}$Ta (shown in figure 3 by open diamonds) and $^9$Be targets, as well as the data of Kwan et al. [64] for the same reactions at 140 MeV/nucleon. These pick-up products have cross sections lower by a factor of 10 or more compared to the present 15 MeV/nucleon reactions. Qualitatively, this can be attributed to the short contact time of the projectile with the target that prevents extensive nucleon exchange, which of course takes place in the lower energy (e.g. 15 MeV/nucleon) reactions. From the above comparisons, we understand that the reactions of choice at our energy of 15 MeV/nucleon are those with the neutron-rich target of $^{238}$U, since they lead to especially enhanced production of the most neutron-rich isotopes.

It is interesting to note that the reaction with the $^{238}$U target leads to substantially enhanced cross sections for neutron-rich nuclides far from the projectile, e.g. for Si, Al and Mg isotopes in figure 3. The cross sections for the most neutron-rich of these isotopes (e.g. $^{35}$Al, $^{32}$Mg) are more than two orders of magnitude larger than those obtained with the $^{64}$Ni target in our reactions at 15 MeV/nucleon (or with the projectile fragmentation reactions). This enhanced production has been experimentally observed in our previous work with $^{86}$Kr(25MeV/nucleon)+$^{208}$Pb and successfully described with the DIT/SMM model framework mainly as asymmetric binary decay of extremely neutron-rich quasiprojectiles [59,60].

5 Angular distributions of projectile fragments from $^{40}$Ar reactions at 15 MeV/nucleon

To understand the kinematics and the angular spread of the fragments from the reactions of the $^{40}$Ar projectile at 15 MeV/nucleon, in figure 4(a) we show the DIT/SMM calculated mass-resolved angular distributions for the $^{40}$Ar+$^{64}$Ni system for which the grazing angle is 7.0°. The successive contours (starting from the innermost) represent a decrease in the yield by a factor of two. The pair of horizontal full lines represent the polar angular acceptance of the MARS spectrometer in the experimental setup of ref. [43] (section 2). The pair of horizontal dashed lines indicate the angular acceptance of the KOBRA separator [65], that we consider as a representative large-acceptance separator especially designed for rare-isotope production at this energy regime in the upcoming RIB facility RISP [12]. In the KOBRA setup, we assume that the beam hits the primary target at an angle of 5° (that may be achieved with the aid of an appropriate beam swinger system) and fragments are collected in the polar angular range of 0°–10° in a solid angle of $\Delta \Omega = 50$ msr.

From the figure, we qualitatively appreciate the issue of the relatively limited angular acceptance of a medium acceptance separator like MARS. Our simulations indicate that a fraction of $\sim$5% (taking into account the azimuthal
acceptance also) of the produced near-projectile fragments falls in the angular acceptance of the MARS spectrometer. However, with an advanced large-acceptance separator like KOBRA, a larger fraction of near-projectile fragments (that can reach 50–80%) can be collected, provided that we swing the primary beam at the appropriate angle (that we can choose to be near the grazing angle of the reaction).

In figure 3(b), we show the mass resolved angular distributions for the reaction of $^{40}$Ar (15 MeV/nucleon) with the heavier target $^{238}$U. The grazing angle for this system is 20.0°. We clearly see that the angular distribution of the near-projectile fragments is much broader, making the efficient collection of the fragments especially challenging. For this reaction, the optimal angle to send the beam on the target (or, equivalently, to rotate a large acceptance spectrometer) is 18°, thus, collecting the fragments in the polar angular range of 13–23°. With a solid angle acceptance of $\Delta \Omega = 50$ msr, the collection efficiency can reach 20–30%. We note, however, that the current design of the KOBRA spectrometer allows the beam to be sent on the target with a maximum angle of 12°, in which case the collection efficiency may be lower by a factor of 2.

From a practical standpoint, the use of the lighter target is preferable, as it leads to narrower angular distributions and thus larger collection efficiency, which may be desirable for certain applications. However, the enhanced production of the most exotic nuclides obtained with the $^{238}$U target, encourages the development of approaches for the efficient collection of fragments from these reactions. In closing, we mention that our event-by-event simulations may allow full event tracking of the products through the beam-optical elements of the separator. Consequently rates for the production and separation of desired neutron-rich nuclides can be determined, as is currently being performed by members of the KOBRA team at RISP.

6 Reactions with a $^{48}$Ca projectile at 15 MeV/nucleon

The above calculations for the $^{40}$Ar (15 MeV/nucleon) projectile are in fair agreement with the experimental data giving us confidence on the reliability of the models used. Moreover, the results of the reactions with $^{238}$U showed us that this target offers the possibility of enhanced production of the most neutron-rich nuclides. Motivated by these promising results, we proceeded to perform calculations with the most neutron-rich stable beam in this mass range, namely $^{48}$Ca at 15 MeV/nucleon for which there are no experimental data at present.

In figure 5, we show our DIT/SMM calculations for the reactions $^{48}$Ca (15
MeV/nucleon) + $^{64}$Ni [solid (red) line] and $^{48}$Ca (15 MeV/nucleon) + $^{238}$U [dashed (blue) line]. In addition, we present the projectile fragmentation data of Mocko et al. [66,67] for the reaction $^{48}$Ca (140 MeV/nucleon) + $^{181}$Ta (open circles).

At first, observations similar to those for figure 3 pertain here. We see that both the $^{48}$Ca+$^{64}$Ni and $^{48}$Ca+$^{238}$U reactions at 15 MeV/nucleon lead to substantial yields of neutron pickup products with the latter reaction offering higher yields. Interestingly, the fragmentation of $^{48}$Ca at 140 MeV/nucleon with the heavy neutron-rich $^{181}$Ta (N/Z=1.48) target leads to the production of neutron pickup products with cross sections nearly similar to those calculated for the $^{48}$Ca(15 MeV/nucleon)+$^{64}$Ni reaction. (We mention that such nuclides are also produced in the fragmentation of $^{48}$Ca (140 MeV/nucleon) on the $^9$Be target with cross sections lower by at least a factor of 10.) It would be interesting to describe theoretically the neutron pickup products from typical fragmentation reactions on heavy targets (e.g. $^{181}$Ta, $^{208}$Pb, $^{238}$U) at the energy of $\sim$100 MeV/nucleon, which is at the lower limit of the typical projectile fragmentation mechanism [68,69]. In the near future, we plan to undertake such a project using our theoretical model framework. In regards to higher energy projectile fragmentation, for completeness, we report the work of Suzuki et al., [70] on $^{48}$Ca (345 MeV/nucleon) + $^9$Be, in which no pickup products were reported. The most neutron-rich isotopes observed were proton-removal products with cross sections similar to those of the 140 MeV/nucleon data of Mocko et al. [66].

7 Reactions with the radioactive beams of $^{46}$Ar and $^{54}$Ca at 15 MeV/nucleon

After the above calculations and comparisons on reactions with the stable beams of $^{40}$Ar and $^{48}$Ca, we continue our study with reactions involving the neutron-rich radioactive beams (RIB) of $^{46}$Ar (Figs. 6 and 7) and $^{54}$Ca (Figs. 8 and 9). We chose these neutron-rich projectiles as representative examples of RIB in this mass range, having six more neutrons than their stable counterparts $^{40}$Ar and $^{48}$Ca, respectively.

In figure 6, we show the DIT/SMM calculations for the RIB reaction $^{46}$Ar (15 MeV/nucleon) + $^{64}$Ni [dashed (blue) line] compared with the calculation for the stable-beam reaction $^{40}$Ar (15 MeV/nucleon) + $^{64}$Ni and our experimental data (closed points) as in figure 2. We observe that the RIB leads to an isotope distribution with a neutron-rich side displaced by several neutrons (nearly six for near-projectile elements) compared with that of the stable beam. We also notice that the enhanced production of the neutron-rich isotopes offered by the RIB diminishes substantially for products further away from the projectile
(see also \[44\], figure 9). In figure 7, we show the DIT/SMM calculations for the reactions of $^{46}$Ar (15 MeV/nucleon) with $^{64}$Ni [solid (red) line] and $^{238}$U [dashed (blue) line]. As expected, we notice that the $^{238}$U target leads to enhanced neutron-rich isotope production, compared with the $^{64}$Ni target, especially at the tails of the distributions for near-projectile elements.

Continuing our discussion, in figure 8, we show the DIT/SMM calculations for the RIB reaction $^{54}$Ca (15 MeV/nucleon) + $^{64}$Ni [dashed (blue) line] compared with the calculations for the stable-beam reaction $^{48}$Ca (15 MeV/nucleon) + $^{64}$Ni [solid (red) line]. As in figure 6, we observe that the RIB results in an isotope distribution with a neutron-rich side displaced to the right compared with that of the stable beam. Finally, in figure 9, we compare the DIT/SMM calculations for the reactions of $^{54}$Ca (15 MeV/nucleon) with $^{64}$Ni [solid (red) line] and $^{238}$U [dashed (blue) line]. Observations similar to those of figure 7 pertain here. Moreover, we notice that extremely neutron-rich and even new isotopes toward $^{60}$Ca are produced in the reaction with the $^{238}$U target.

8 Isotope production rates

A comprehensive presentation on the Z-N plane of the DIT/SMM calculated production cross sections of projectile fragments from the 15 MeV/nucleon reactions $^{48}$Ca + $^{238}$U and $^{54}$Ca + $^{238}$U is given in figure 10. In this figure, stable isotopes are represented by closed squares, whereas fragments obtained by the respective reactions are given by the open circles (with sizes corresponding to cross-section ranges according to the figure key). The solid (red) line gives the expected location of the neutron drip line as calculated in Ref. [74]. In the figure, we clearly observe that the neutron pickup products from the radioactive beam reaction (figure 10b) extend toward the region of the neutron drip line near $^{62}$Ca.

We now proceed to a discussion of the production rates of some representative neutron-rich rare isotopes. In table 1, we show the DIT/SMM calculated cross sections and the predicted production rates of some isotopes from the reaction $^{48}$Ca (15 MeV/nucleon) + $^{238}$U. We assume a beam intensity of 500 particle nA (3x10$^{12}$ particles/s) and a target thickness of 20 mg/cm$^2$.

Subsequently, in table 2, we show the predicted cross sections and production rates of several isotopes from the reaction of a radioactive beam of $^{46}$Ar (15 MeV/nucleon) with $^{238}$U. In this case, we assumed that the beam intensity is equal to the production rate of $^{46}$Ar from the reaction $^{48}$Ca (15 MeV/nucleon) + $^{238}$U (table 1) and that the target thickness is again 20 mg/cm$^2$. We see that very exotic nuclei such as $^{52}$Ar and $^{49}$Cl can be produced with rates that may allow spectroscopic studies.
Table 1
Calculated cross sections (with DIT/SMM) and rates of neutron-rich isotopes from the stable-beam reaction \( ^{48}\text{Ca} (15\text{ MeV/nucleon}) + ^{238}\text{U} \). For the rates, the beam intensity is assumed to be 500 \( \text{pnA} \) \((3 \times 10^{12} \text{ particles/sec})\) and the target thickness 20 \( \text{mg/cm}^2 \). Isotope halflives are taken from [73,74].

| Rare isotope | \( t_{1/2} \) (s) | Reaction channel | Cross section (mb) | Rates (s\(^{-1}\)) |
|-------------|--------------------|------------------|--------------------|---------------------|
| \( ^{54}\text{Ca} \) | 0.09               | -0p + 6n         | 0.030              | 4.6 \times 10^3     |
| \( ^{46}\text{Ar} \) | 8.4                | -2p + 0n         | 2.9                | 4.4 \times 10^5     |
| \( ^{55}\text{Sc} \) | 0.09               | +1p + 6n         | 0.050              | 7.8 \times 10^3     |
| \( ^{52}\text{K} \)   | 0.10               | -1p + 5n         | 0.050              | 7.8 \times 10^3     |

Table 2
Calculated cross sections (with DIT/SMM) and rates of neutron-rich isotopes from the radioactive-beam reaction \( ^{46}\text{Ar} (15\text{ MeV/nucleon}) + ^{238}\text{U} \). For the rates, the beam intensity is assumed to be \( 4.4 \times 10^5 \) particles/sec and the target thickness 20 \( \text{mg/cm}^2 \). Isotope halflives are taken from [73,74].

| Rare isotope | \( t_{1/2} \) (ms) | Reaction channel | Cross section (mb) | Rates (h\(^{-1}\)) |
|-------------|-------------------|------------------|--------------------|---------------------|
| \( ^{51}\text{Ar} \) | 24                | -0p + 5n         | 0.064              | 5.0                 |
| \( ^{52}\text{Ar} \) | 16                | -0p + 6n         | 0.008              | 0.6                 |
| \( ^{48}\text{Cl} \) | 39                | -1p + 3n         | 0.24               | 18                  |
| \( ^{49}\text{Cl} \)   | 28                | -1p + 4n         | 0.064              | 5.0                 |

Finally, in table 3, we show the predicted cross sections and production rates of nuclides from the reaction of a radioactive beam of \( ^{54}\text{Ca} (15\text{ MeV/nucleon}) \) with \( ^{238}\text{U} \). As before, we assumed a beam intensity equal to the production rate of \( ^{54}\text{Ca} \) from the reaction \( ^{48}\text{Ca} (15\text{ MeV/nucleon}) + ^{238}\text{U} \) (table 1) and a target thickness of 20 \( \text{mg/cm}^2 \). We notice that relatively low but "usable" rates of extremely rare and even new isotopes, like \( ^{59}\text{Ca} \) (~1 per day) and \( ^{60}\text{Ca} \) (~1 per week) can be produced that may allow to obtain identification and basic spectroscopic information for such nuclides.

9 Discussion and Plans

We would like to conclude the present study with some comments on the model approaches used in this work. Starting from the microscopic CoMD model used in the dynamic stage, we think that the successful description of the reactions is especially valuable due to the predictive power of the microscopic many-body approach, as we have also seen in our recent works [44,54,17], that does
Table 3
Calculated cross sections (with DIT/SMM) and rates of neutron-rich isotopes from
the radioactive-beam reaction $^{54}$Ca (15 MeV/nucleon) + $^{238}$U. For the rates, the
beam intensity is assumed to be $4.6 \times 10^3$ particles/sec and the target thickness 20
mg/cm$^2$. Isotope half-lives are taken from [73,74]. (Theoretical estimates for new
nuclides are marked with an asterisk.)

| Rare isotope | $t_{1/2}$ (ms) | Reaction channel | Cross section (mb) | Rates (d$^{-1}$) |
|--------------|---------------|------------------|--------------------|-----------------|
| $^{57}$Ca    | 7             | -0p + 3n         | 0.60               | 12              |
| $^{58}$Ca    | 12            | -0p + 4n         | 0.16               | 3.2             |
| $^{59}$Ca    | 6*            | -0p + 5n         | 0.040              | 0.80            |
| $^{60}$Ca    | 4*            | -0p + 6n         | 0.008              | 0.16            |
| $^{54}$K     | 10            | -1p + 1n         | 0.57               | 11              |
| $^{55}$K     | 4             | -1p + 2n         | 0.13               | 2.6             |

not depend on ad hoc assumptions of the reaction dynamics. We saw that the
two-stage CoMD/SMM approach provided good results in comparison with
the experimental data. Nonetheless, we point out that it is very computer
intensive due to the N-body CoMD stage of the calculation [44], that limited
its extensive application in this work. On the contrary, the phenomenological
DIT/SMM approach, offering results similar to the microscopic CoMD/SMM
approach, is rather fast. For this reason we used it extensively in this study
to estimate cross sections of very neutron-rich products. Moreover, this ap-
proach can be practical for the design of RIB experiments based on the present
reactions.

As a continuation of the present work, we plan to perform systematic CoMD
calculations toward the region of very low cross sections and compare them
with the corresponding DIT results. Furthermore, we plan to continue the
systematic calculation efforts with radioactive beams that are expected from
upcoming RIB facilities in the energy range of 10–25 MeV/nucleon. Concerning
the choice of energy, our calculations, presented in the appendix, suggest
that the energy of 15 MeV/nucleon is a reasonable choice for the efficient pro-
duction of very neutron-rich isotopes close to the projectile. This conclusion
is also in agreement with our previous experimental [43] and theoretical [44]
work. Since our calculations are complete event-by-event simulations, we can
also study systematically the velocity distributions, the angular distributions
and, the ionic charge state distributions of the projectile fragments. This infor-
mentation can form the basis of realistic beam optics simulations of the behavior
of large acceptance separators and may help us optimize our ability to separate
and identify exotic neutron-rich nuclides.

In the near future, apart from systematic RIB calculations in the mass range
40–60, we plan to perform detailed measurements of projectile fragments from $^{48}\text{Ca}$ and $^{70}\text{Zn}$ beams at 10–15 MeV/nucleon a) at Texas A&M with the MARS recoil separator [42,43] and b) at LNS/INFN with the MAGNEX large-acceptance spectrometer [71]. We expect that these measurements will provide a further detailed testing ground for our models, and will offer access to very neutron-rich nuclei for a broad range of studies. These studies may include measurements of secondary reactions, in-beam spectroscopy of selected products, decay measurements and further search for new isotopes or new isomers. In parallel, these efforts will provide experience and preparation for future plans at upcoming large-acceptance separator facilities (e.g. KOBRA [65], ISLA [72]).

10 Summary and conclusions

In this article we report on our continued efforts to systematically study the production of neutron-rich rare isotopes with heavy-ion beams in the energy range of 15–25 MeV/nucleon. We studied the production of neutron-rich projectile-like isotopes in multinucleon transfer collisions of stable and radioactive beams in the mass range $A \sim 40–60$. We first presented our experimental cross section data on $^{40}\text{Ar}(15\text{ MeV/nucleon}) + ^{64}\text{Ni}$, $^{58}\text{Ni}$ and $^{27}\text{Al}$ and compared them with calculations. The calculations are based on two models: the phenomenological deep-inelastic transfer (DIT) model and the microscopic constrained molecular dynamics (CoMD) model employed to describe the dynamical stage of the collision. De-excitation of the resulting projectile-like fragments is performed with the statistical multifragmentation model (SMM). An overall good agreement of the calculations with the experimental data is obtained. We also performed calculations of the reaction of $^{40}\text{Ar}$ (15 MeV/nucleon) projectile with the heavy neutron-rich target of $^{238}\text{U}$. We then continued with the reactions of the neutron-rich beam of $^{48}\text{Ca}$ (15 MeV/nucleon) with targets of $^{64}\text{Ni}$ and $^{238}\text{U}$. In these reactions, we observed that neutron-rich rare isotopes with substantial cross sections can be produced which, in turn, may be assumed to form radioactive beams and interact with a subsequent target, preferably $^{238}\text{U}$, resulting in extremely neutron-rich and even new isotopes (e.g. $^{60}\text{Ca}$) in this mass range. We conclude that multinucleon transfer reactions with stable or radioactive beams at the energy of around 15 MeV/nucleon constitute a novel and competitive route to access extremely neutron-rich rare isotopes that may open up exciting nuclear research opportunities in current or upcoming rare isotope beam facilities.
11 Acknowledgements

We are thankful to L. Tassan-Got for the DIT code, M. Papa and for his version of the CoMD code and A. Botvina for the SMM code. We also thank A. Pakou, O. Sgouros and V. Soukeras for numerous enlightening discussions and suggestions. Financial support for this work was provided, in part, by the National and Kapodistrian University of Athens under ELKE Research Account No 70/4/11395 and, in part, by the US Department of Energy through Grant No. DEFG02-93ER40773 and the Robert A. Welch Foundation through Grant No. A-1266. K.T., S.C.J and B.H.K and Y.K.K were supported by the Rare Isotope Science Project of the Institute for Basic Science funded by the Ministry of Science, ICT and Future Planning and National Research Foundation of Korea. M.V. was supported by the Slovak Scientific Grant Agency under contracts 2/0105/11 and 2/0121/14 and by the Slovak Research and Development Agency under contract APVV-0177-11.

12 APPENDIX: Energy dependence of production cross sections

In this appendix, we examine the dependence of the cross sections of the neutron-rich products on the projectile energy. We consider the stable-beam reaction of $^{48}$Ca with the $^{238}$U target and performed DIT/SMM calculations at beam energies of 10, 15 and 25 MeV/nucleon. The results are presented in figure 10 by dashed (blue), solid (black) and dotted (red) lines, respectively. We observe that on the neutron-rich side, the reactions at the lower two energies, 10 and 15 MeV/nucleon, lead to nearly similar cross sections which are higher than those of the reaction at 25 MeV/nucleon. On the neutron-deficient side, the distributions of the 15 and 25 MeV/nucleon reactions are similar, indicating a possible similarity of the excitation energies of the quasiprojectiles leading to these isotopes. At 10 MeV/nucleon, the neutron-deficient nuclide cross sections are lower as a result of lower excitation energies reached in this reaction compared to the higher energy ones. The above comparisons lead us to the conclusion that the beam energy of 15 MeV/nucleon is a reasonable choice for the efficient production of the most neutron-rich nuclides in these multinucleon transfer reactions.

Fig. 1. (Color online) Experimental mass distributions (cross sections) of the isotopes of elements Z=19–12 for the three reactions measured: $^{40}$Ar (15 MeV/nucleon) + $^{64}$Ni, $^{58}$Ni, $^{27}$Al, represented by closed (black) circles, open (red) circles and open (blue) squares, respectively. Nuclides to the left of the thin solid lines are not fully covered by the magnetic rigidity range of the experiment (see text). Nuclides with a net pickup of neutrons from the target lie to the right of the dotted lines.
Fig. 2. (Color online) Comparison of calculated mass distributions (lines) of projectile fragments with $Z=19$–12 from the reaction $^{40}$Ar (15 MeV/nucleon) + $^{64}$Ni with the experimental data [closed (black) circles, as in figure 1]. The calculations are: DIT/SMM [solid (red) line] and CoMD/SMM [dashed (blue) line]. Nuclides to the left of the thin solid lines are not fully covered by the magnetic rigidity range of the experiment (see text). Nuclides with a net pickup of neutrons from the target lie to the right of the dotted lines.
Fig. 3. (Color online) DIT/SMM calculated mass distributions (cross sections) of projectile fragments with Z=19–12 from the reaction $^{40}$Ar (15 MeV/nucleon) + $^{238}$U [dashed (blue) line] compared with those from $^{40}$Ar (15 MeV/nucleon) + $^{64}$Ni [solid (red) line] and the experimental data [closed (black) circles]. Nuclides to the left of the thin solid lines are not fully covered by the magnetic rigidity range of the experiment (see text). Nuclides with a net pickup of neutrons from the target lie to the right of the dotted lines. In addition, the projectile fragmentation data of $^{62}$ on $^{40}$Ar (94 MeV/nucleon) + $^{181}$Ta are presented by open circles and those of $^{63}$ of the same system at 57 MeV/nucleon by open diamonds.
Fig. 4. (Color online) (a) DIT/SMM calculated mass-resolved angular distributions of projectile fragments from the reaction $^{40}$Ar (15 MeV/nucleon) + $^{64}$Ni. The successive contours (starting from the innermost) represent a decrease in the yield by a factor of two. The solid (green) lines represent the polar angular acceptance of the MARS spectrometer, and the dashed (blue) lines the optimum angular acceptance of the KOBRA spectrometer for this reaction. The arrow indicates the grazing angle of the Ar+Ni reaction (in the lab system). (b) As in panel (a), but for the reaction $^{40}$Ar (15 MeV/nucleon) + $^{238}$U. In this case, the angular acceptance of KOBRA corresponds to the maximum angle of the beam on the target (see text).
Fig. 5. (Color online) DIT/SMM calculated mass distributions (cross sections) of projectile fragments with Z=21–14 from the reactions $^{48}$Ca (15 MeV/nucleon) + $^{64}$Ni, $^{238}$U compared with the projectile fragmentation data of Ref. [66,67] on $^{48}$Ca (140 MeV/nucleon) + $^{181}$Ta [open (black) circles]. Nuclides with a net pickup of neutrons from the target lie to the right of the dotted lines.
Fig. 6. (Color online) DIT/SMM calculated mass distributions (cross sections) of projectile fragments with Z=19–12 from the radioactive-beam reaction $^{46}$Ar (15 MeV/nucleon) + $^{64}$Ni [dashed (blue) line] compared with the stable-beam reaction $^{40}$Ar (15 MeV/nucleon) + $^{64}$Ni [solid (red) line] and the experimental data [closed (black) circles]. As in Figs. 1–3, nuclides to the left of the thin solid lines are not fully covered by the magnetic rigidity range of our 15 MeV/nucleon experiment.
Fig. 7. (Color online) DIT/SMM calculated mass distributions (cross sections) of projectile fragments with Z=19–12 from the reaction of a radioactive-beam of $^{46}$Ar (15 MeV/nucleon) on $^{64}$Ni [solid (red) line] and $^{238}$U [dashed (blue) line]. Nuclides with a net pickup of neutrons from the target lie to the right of the dotted lines.
Fig. 8. (Color online) DIT/SMM calculated mass distributions (cross sections) of projectile fragments with Z=21–14 from the radioactive-beam reaction $^{54}$Ca (15 MeV/nucleon) + $^{64}$Ni [dashed (blue) line] compared with the stable-beam reaction $^{48}$Ca (15 MeV/nucleon) + $^{64}$Ni [solid (red) line].
Fig. 9. (Color online) DIT/SMM calculated mass distributions (cross sections) of projectile fragments with $Z=21$–14 from the reaction of a radioactive-beam of $^{54}$Ca (15 MeV/nucleon) on $^{64}$Ni [solid (red) line] and $^{238}$U [dashed (blue) line]. Nuclides with a net pickup of neutrons from the target lie to the right of the dotted lines.
(15 MeV/nucleon) $^{48}$Ca, $^{54}$Ca + $^{238}$U

Fig. 10. (Color online) (Color online) Representation on the Z–N plane of DIT/SMM calculated production cross sections of projectile fragments from 15 MeV/nucleon reactions of (a) the stable beam $^{48}$Ca with $^{238}$U, and (b) the radioactive-beam $^{54}$Ca with $^{238}$U. The cross section ranges are shown by open circles according to the key. The closed squares show the stable isotopes. The solid (red) line represents the expected location of the neutron drip line according to [74]. The horizontal and vertical dotted line segments indicate the location of the projectiles.
Fig. 11. (Color online) Energy dependence of DIT/SMM calculated mass distributions of projectile fragments with $Z=21–14$ from the reaction of a $^{48}$Ca beam with a $^{238}$U target at energies of 10, 15 and 25 MeV/nucleon represented by dashed (blue), solid (black) and dotted (red) lines respectively. Nuclides with a net pickup of neutrons from the target lie to the right of the dotted lines.
