**Temperature-Dependence of the Rates of Reaction of Trifluoroacetic Acid with Criegee Intermediates**

**Rabi Chhantyal-Pun,* Max R. McGillen, Joseph M. Beames, M. Anwar H. Khan, Carl J. Percival, Dudley E. Shallcross, and Andrew J. Orr-Ewing***

**Abstract:** The rate coefficients for gas-phase reaction of trifluoroacetic acid (TFA) with two Criegee intermediates, formaldehyde oxide and acetone oxide, decrease with increasing temperature in the range 240–340 K. The rate coefficients $k(CH_2OO + CF_3COOH) = (3.4 ± 0.3) \times 10^{-10} \text{cm}^3\text{s}^{-1}$ and $k((CH_3)_2COO + CF_3COOH) = (6.1 ± 0.2) \times 10^{-10} \text{cm}^3\text{s}^{-1}$ at 294 K exceed estimates for collision-limited values, suggesting rate enhancement by capture mechanisms because of the large permanent dipole moments of the two reactants. The observed temperature dependence is attributed to competitive stabilization of a pre-reactive complex. Fits to a model incorporating this complex formation give $k[\text{cm}^3\text{s}^{-1}] = (3.8 ± 2.6) \times 10^{-16} T^2 \exp((1620 ± 80)/T) + 2.5 \times 10^{-10} T^2 \exp((1620 ± 230)/T) + 5.2 \times 10^{-10}$ for the $CH_2OO + CF_3COOH$ and $(CH_3)_2COO + CF_3COOH$ reactions, respectively. The consequences are explored for removal of TFA from the atmosphere by reaction with biogenic Criegee intermediates.

Halogenated organic acids such as trifluoroacetic acid (TFA) form in the Earth’s troposphere by oxidation of anthropogenically produced hydrofluorocarbons (HFCs), hydrochlorofluorocarbons (HCFCs) and hydrofluoro-olefins (HFOs), and also have natural sources. They react only slowly with hydroxyl radicals and do not photolyse at ambient wavelengths. Current atmospheric models therefore incorporate surface deposition and rain-out as their main loss processes. However, recent evidence from laboratory studies indicates that organic acids, and other trace atmospheric molecules, react with Criegee intermediates with room-temperature rate coefficients that approach (or exceed) the expected gas-kinetic limits predicted by collision rates. Barrierless reaction pathways have been identified computationally, corroborating the experimental measurements. These reactions might therefore represent a significant chemical loss mechanism for halogenated organic acids from the troposphere.

Here, we examine the temperature dependence of the reactions of $CH_2OO$ and $(CH_3)_2COO$ with TFA, which we selected as representative of Criegee intermediate reactions with halogenated organic acids. We present rate coefficients measured over a range of temperatures spanning those encountered in the lower troposphere. Bimolecular rate coefficients were determined by the pseudo-first-order kinetic method for $CH_2OO + CF_3COOH$ ($k_1$), $CH_2OO + CF_3COOD$ ($k_2$) and $(CH_3)_2COO + CF_3COOH$ ($k_3$) reactions for temperatures from 240 to 340 K and pressures from 10 to 100 torr. The measurements used cavity ring-down spectroscopy methods described previously and in Supporting Information (SI).

Complementary quantum chemistry calculations provided energies and structures along the reaction pathways to aid interpretation of the kinetic measurements, and to guide predictions of rates of as-yet unstudied reactions. Stationary points involved in the reactions of $CH_2OO$, $(CH_3)_2COO$, anti-C((trans-CH)=CH2)-CHO (anti-methacrolein oxide) and syn-CH3-trans-(CH=CH2)COO (syy-methyl vinyl ketone oxide) with $CF_3COOH$ were calculated at the DF-HF/DF-LCCSD(T)-F12a/aug-cc-pVTZ//B3LYP/6-31+G(d) level of theory. The former two reactants serve as model systems, whereas the latter two were selected as possible Criegee intermediate products of the ozonolysis at each of the C–C bonds of isoprene, an important tropospheric constituent with biogenic sources. Their structures are shown in the SI. Similarities between the calculated reaction paths allow predictions of rates of reaction of TFA with the Criegee intermediates from isoprene ozonolysis which we incorporate into atmospheric chemistry models.

Figure 1 shows an example of the method for determination of $k_2$ for the $CH_2OO + CF_3COOD$ reaction. The $CH_2OO$ decay traces in the presence of different $CF_3COOD$ concentrations were fitted with a simultaneous first- and second-order decay fit function:

$$\Delta x(t) = \frac{k_2}{k_1+k_2}e^{-k_2t} - k_1 \left( \frac{t}{k_1} \right) + k_2 \left( \frac{t}{k_2} \right) e^{-k_2t}$$

(1)
The inset shows the pseudo-first-order decay rate coefficients plotted against CF$_3$COOD concentration. The lowest and highest concentration measurements were repeated to ensure reproducibility. The solid line in the inset plot is a linear fit from which the bimolecular rate coefficient is obtained.

In Equation (1), $\Delta k(t)$ is the change in the cavity ring-down rate coefficient at different time delays and $k' = k_{2,1}/\sigma_{355 \text{ nm}}$ is the second-order decay rate coefficient for the bimolecular self-reaction of the Criegee intermediate scaled by its absorption cross section at a probe wavelength of 355 nm. The parameter $k_p$ is the rate coefficient for the TFA + Criegee intermediate reaction under pseudo-first-order conditions. $L$ and $d$ are the cavity length and the overlap length of the photolysis and probe lasers, and $c$ is the speed of light. The first-order component accounts for both unimolecular decomposition and reaction with excess CF$_3$COOD. The bimolecular self-reaction of CH$_2$OO was observed to have a temperature dependence, which was included in the fitting model. The gradients of plots of $k_p$ against CF$_3$COOD concentration provide the $T$-dependent bimolecular reaction rate coefficients, whose statistical errors varied from 1.5 to 5.7%. Similar measurements were undertaken for the CH$_3$OO + CF$_3$COOH reaction. At all the temperatures studied, H/D substitution of the TFA had no significant effect on the measured rate coefficients.

Within the 10–100 torr range examined at $T = 294$ K, there is no significant pressure dependence, and a rate coefficient $k_p(294 \text{ K}) = (3.4 \pm 0.3) \times 10^{-10}$ cm$^3$ s$^{-1}$ is obtained by taking an average and $2\sigma$ uncertainty range of all the measurements. This rate coefficient is greater than the gas-kinetic limiting value of $1.9 \times 10^{-10}$ cm$^3$ s$^{-1}$ at 294 K calculated from collision theory using B3LYP/6-31 + G(d) optimized CH$_3$OO and CF$_3$COOH geometries.

We first consider the information deriving from the observed $T$-dependence of the reaction rates, and then apply the resulting mechanistic understanding to further TFA reactions of atmospheric importance. We previously proposed that the self-reactions of Criegee intermediates follow dipole capture behaviour. In the dipole capture model, the reaction cross section is greater than the physical dimensions of the reactants, and the rate coefficient $k_{2,1}$ is:

$$k_{2,1} = C \sqrt{\pi/\mu} (\mu_1 \mu_2)^{1/2} (k_B T)^{-1/6}$$

Here $\mu_{1,2}$ are the dipole moments of the two reactants, $\mu$ is their reduced mass, $k_B$ is the Boltzmann constant, and $C$ is a constant dependent on the anisotropy of the capture potential. Figure 2 shows a plot of the temperature dependence of the measured rate coefficients $k_3(T)$ for the CH$_2$OO + CF$_3$COOH and (CH$_3$)$_2$COO + CF$_3$COOH reactions. Dashed and solid lines are fits to Equation (2) and (5), respectively.

Figure 3 shows computed energies for stationary points along the minimum energy pathways for the CH$_2$OO + CF$_3$COOH and (CH$_3$)$_2$COO + CF$_3$COOH reactions. The features of both pathways are similar and we focus on the former reaction. A pre-reactive complex coordinated by a hydrogen bond precedes a mostly entropic submerged barrier to reaction. Passage over this transition state, the properties of which are described in the SI, gives a hydroperoxy ester (HPE), CF$_3$COH.CH$_3$OOH. In this product, the H atom from TFA transfers to the CH$_2$OO moiety and the carbonyl O atom of CF$_3$COOH forms a bond with the C atom of CH$_2$OO. This barrierless pathway is consistent with the large experimentally observed rate coefficients (Figure 2), and may account for the absence of an H/D kinetic isotope effect.

A second pathway (not shown in Figure 3) involving a different pre-reactive complex, stabilized by dual hydrogen bonds (DHBs), is expected on the basis of prior computa-
returns $A = (3.8 \pm 2.6) \times 10^{-18}$ cm$^3$ s$^{-1}$ K$^{-2}$ and $\Delta H = 13.1 \pm 1.5$ kJ mol$^{-1}$. The latter corresponding to a reaction in which the binding energy for the DHB complex is greater than the activation barrier to its reaction(s). This value is consistent with the computed enthalpy changes $\Delta H_{A} \approx 48.5$ kJ mol$^{-1}$ and $\Delta H_{B} \approx 41$ kJ mol$^{-1}$ (at the CBS-QB3 level) reported by Long et al. for the CH$_{3}$OO + HCOOH reaction. A similar analysis was conducted for the (CH$_{3})_{2}$COO + CF$_{3}$COOH reaction, giving $A = (4.9 \pm 4.1) \times 10^{-18}$ cm$^3$ s$^{-1}$ K$^{-2}$ and $\Delta H = 13.1 \pm 1.9$ kJ mol$^{-1}$. These fit outcomes and the corresponding entropy changes are summarized in Table S5 in the SI.

The computational methodology used for reactions of TFA with CH$_{3}$OO and (CH$_{3})_{2}$COO can also be applied to its reactions with Criegee intermediates from the ozonolysis of biogenic isoprene. Computed pathways for reactions of these Criegee intermediates with CF$_{3}$COOH are found to be analogous to those in Figure 3 (see SI). The similarities indicate that the isoprene-derived Criegee intermediate reactions (and, by extension, those of other biogenic Criegee intermediates) will approach dipole-capture limited values and show similar $T$-dependences to the CH$_{3}$OO and (CH$_{3})_{2}$COO + CF$_{3}$COOH reactions. These deductions allow us to predict the loss rate of TFA in the atmosphere by reaction with the most tropospherically abundant Criegee intermediates.

Figure 4 shows computed global CF$_{3}$COOH loss rates from reactions with Criegee intermediates, as a percentage of the overall TFA loss rate. The SI provides details of the

[Image: Figure 3. Minimum energy pathways for a) CH$_{3}$OO + CF$_{3}$COOH and b) (CH$_{3})_{2}$COO + CF$_{3}$COOH reactions, with structures and their energies calculated at the DF-HF/DF-LCCSD(T)-F12a/au-g-cc-pVTZ//B3LYP/6-31+G(d) level of theory. Energies, given in kJ mol$^{-1}$, are specified relative to those of the reactants (at the far left) and are shown as both reaction enthalpies and Gibbs free energies. RC, TS and P denote pre-reactive complexes, transition states and products.

condensation to secondary organic aerosol (SOA). Competition between SOA formation, solar photodissociation, and adduct hydrolysis will then have consequences for the distribution of TFA and other halogenated organic acids in the environment.

Temperature-Dependence of the Rates of Reaction of Trifluoroacetic Acid with Criegee Intermediates

Criegee intermediates produced by ozonolysis of alkenes in the Earth’s troposphere are potentially important oxidizers of trace constituent gases. Studies of the rates of reaction of trifluoroacetic acid with two Criegee intermediates, formaldehyde oxide and acetone oxide, suggest an important atmospheric sink for this persistent pollutant.
