ABSTRACT

Earth has been used worldwide as a building material for centuries and it is still one of the most used construction materials. In many countries the excavated soil is becoming one of the largest construction waste and its disposal is costly and problematic. For this reason, there is a rising interest in employing the excavated soil directly in field, possibly as an added value construction material. In this paper a new type of rammed earth is presented. This new material is based on the shotcrete technology and has been named shot-earth. A mix of stabilized soil, aggregates and water is consolidated by high speed projection rather than by mechanical compaction to obtain both structural and non-structural elements. The first characterization of the physical properties of this material has shown the great potential of this technology.

1. Introduction

Soil has been used to construct for centuries with different methods and technologies. Largely replaced by other materials, the soil is nevertheless still in use in many areas of the world (see Fig. 1) and it is still one of the most used construction materials. In many areas of the world, such as France, the soil is particularly adapted to construct because it contains an appropriate quantity of clay. The earth construction has demonstrated to be durable in many contexts as shown by the ancient city of Shibam (see Fig. 2a) entirely constructed in soil and still populated. Furthermore, many architects have succeeded in using earth to construct modern and durable buildings (see Fig. 2b).

The vernacular construction techniques [7] have evolved such that today are available in the market products such as the "earth concrete" [20]. Among the "earth concretes" that have reached a certain popularity there are the Alker and the Cast Earth [40]. Researchers have found a method to produce self-leveling earth concrete based on the use of clayey soil and CSA binders [9,16]. Many are also the applications of soil placed by projection, most of these are developed for rendering but attempts to construct walls and houses using projection have been made [3]. Not all the soil is adapted to construct and in these cases other construction techniques have been developed and used (stone and brick masonry, wood, etc.). In other cases the performances of soil have been improved by stabilization [7,2]. In the past the stabilization of soil was performed by instance by adding straw, rosins and arabinic gums while today the stabilization of soil is made by adding binder such as lime, gypsum, different types of cements and magnesium oxides. The high energy compaction methods can also be viewed as a form of stabilization [1]. Stabilization is fundamental to improve a soil that is not adapted for construction and it is widely studied worldwide. In particular, Fig. 3 shows that enhancing the mechanical performances (particularly in terms of strength and durability) of crude earth by manipulating its clay fraction might be an effective low-cost approach to avoid various drawbacks linked to the use of Portland as stabilization [20]. Nevertheless, it is remarked that this might be true for clayey soils.

Despite the renewed interest on the soil construction, the codes and practices for structural design remain schematic for vernacular and modern soil-based structures. The technique presented in this paper, named “shot earthcrete” or “shot-earth” is a new technology based on the high-speed projection (spraying) of a mix of stabilized soil, aggregates and water. Being based on a dry process, the quantity of water in the mix is low and the quantity and type of the stabilization is chosen according to the quality of the excavated soil and the application targeted. Given the lack of norms and codes of practice the characterization of the shot-heart is therefore mandatory in order to understand the behavior of this new material under load. In this research a particular emphasis was paid to the following issues:

- Shot-earthcrete as construction material;
- Influence of the placing process on the shot-earthcrete;
- Earthcrete as construction technology.

The experimental campaign focused firstly on the identification on the most important mechanical parameters such as ultimate compressive and tensile strengths, Young modulus and Poisson ratio. In a sec-

Fig. 2. Recent constructions realized by using soil as building material.

2. Experimental program

In order to design a load carrying element, some mechanical parameters are needed [21, 22]. For concrete the relationships between many mechanical properties are well known and therefore often it
is sufficient the value of the compressive strength to derive most of the other physical properties. The shot-earth can be considered as a low strength concrete but this could not be assumed before testing. Therefore, standard practices for testing concrete and masonry were adopted to determine parameters such as the Young modulus, Poisson ratio, shear modulus and tensile strength [24–26,29–34]. The experimental program consisted of two phases: the first one aimed at testing prismatic specimens; the second one devoted to investigate both axial and diagonal compression of walls samples. All specimens were cured at \(23 \pm 1.7^\circ\text{C} (73 \pm 3^\circ\text{F})\) of temperature and 50 ± 5% of relative humidity and then tested at 28 days. During the drying process the weight loss was monitored with the aid of a thermal camera.

3. Materials and methods

Shot-earth consists of a dry mix of soil, cement and coarse sand (size 0–8 mm) propelled through a nozzle. The size of the sand and the mix design are determined according to the composition of the excavated soil. In this case the mix proportions were 7/7/2 (7 soil, 7 sand and 2 cement) ratio by weight in the dry mixture. This mix was studied to obtain a strength sufficient to construct vaults and walls, without altering the color of the final product. The mixture is pressurized into a properly designed machine and conveyed through a hose to the spraying nozzle by a high velocity air-stream. About 3% (by volume) of water is injected in the nozzle of water to obtain a certain degree of cohesion and promote the hydration of the cement grains. Water has to be added in a quantity that permits admission of the mix when shot on the mould and to avoid that the mix do not held in place. Furthermore, water should not be in excess to prevent shrinkage. The projection methodology is fundamental to obtain a good result. Two projection methods were tested, one overhead on a closed mould (see Fig. 4b), one on a vertical surface with an angle of approximately 45° (see Fig. 4a). The overhead method proved to be the less effective since it promoted a chaotic movement inside the mould with segregation of the mix (see Fig. 5b). Furthermore, during the spraying process a cloud of dust formed inside the mold, thus preventing the nozzle-man to see where flow of the material should be directed. The overhead technique is therefore more interesting when used on large horizontal surfaces rather than in vertical closed moulds. None of the above-mentioned problems were encountered while using the side projection method, which was therefore chosen for ensuing phases of the testing campaign.

The machine used to shot the stabilized earth is a modified twin chamber machine, similar to the one showed in Fig. 6. This equipment is generally used to shot refractory materials, mixes of dry sand and cement; it is a so-called dry process machine and its production rate equals 10 m\(^3\)/h. This type of dry spray machine is appreciated by practitioners because of its steady rate of feeding into the air stream. This feature allows maintaining a constant water cement ratio and a constant rate of shooting: An unsteady air stream and the ensuing pulsation might cause segregation problem with loss of strength of the material. The dry process also permits to have an excellent “green strength” since the mixture is well compacted and self-sustaining material as soon as it is placed. Therefore, the surfaces can be immediately finished by hand or mechanically, without the risks of damaging the structural elements.

Shot-earth is a method to construct structures and manufacture construction products using soil and also a method to valorize the excavated soil. Basically the soil used in construction should not have a large content of organic matter, therefore 25/50 cm of topsoil should always be removed. The topsoil is also precious for other applications and it should not be damaged or polluted. The presence of pollutants should be checked carefully with techniques such as XRF, XRD and other chemical analyses. Furthermore, the excavated soil should be let dry and then undergoes through a sieving and screening process. Sieving and screening allows removing all aggregates present in the soil and screening will help to obtain an optimal size of the soil particles. Gravel and soil thus obtained are then used to formulate the mix of the shot-earth. In this case a cement CEM I 42.5N was used for stabilization.

4. Specimens

For this testing campaign several specimens were manufactured ([23,27]) and, in particular, two large walls (1 × 1 × 0.3 m\(^3\)) were prepared in order to check the projection method (head on or side) and to extract cores (see Fig. 5a) for direct traction test, thus assessing the quality of the material. Specimen sizes and their use are listed in Table 1.

The drying process of specimens was monitored by means of weighting and by means of thermal camera images (see Fig. 7). The drying process of the specimens was carried out at 20 ± 2 °C of temperature and 50 ± 5% of relative humidity (RH). The specimen weight was monitored using an electronic scale. Fig. 8 illustrates the weight loss in time in order to describe the drying process and the shot-earth curing: From the shot-earth casting, approximately 20 days elapsed before achieving a constant weight of about 132 kg. Therefore the specimen lost around 6.4 kg as the result of drying process [28]. The shot-earth walls manufactured had a bulk density of about 2070 kg/m\(^3\).

5. Results and discussion

5.1. Compressive Test

The compressive strength was determined by using standard test procedure for concrete. In fact this shot-earth mix has shown mechanical properties that resemble those of a low strength concrete.

The machine used for this test was a W + B LFV 200 kN apparatus (see Fig. 10). The compressive test was carried out on five 15 × 15 × 15 cm\(^3\) cubes cured for 28 days. The strength values are listed in Table 2. The failure mode, characterized by the formation of a cone, is admitted by codes and in general the specimens have a brittle failure after achieving their maximum compressive stress (see Fig. 9).

5.2. Young modulus

Young modulus was determined according to EN 12390-13 [36]. The test method allows determining two moduli of elasticity: The initial modulus \(E_{\text{ia}}\) measured at first loading, and the stabilized modulus \(E_{\text{is}}\) measured after three loading cycles (see Fig. 11). The strain evaluation was based on the \\(^*\) curve, with three repetition of loading for measuring the time effect. The \(E_{\text{is}}\) corresponds to the secant slope passing through the origin and to the ordinate point 0.33 \(\varepsilon_1\), namely \(E_{\text{is}} = \varepsilon_1/\varepsilon_3\).

Results listed in Table 3 showed the stabilized Young modulus, which was computed between 5 and 33% of \(\sigma_1\) by linear fitting; it showed relatively low scattering and \(E_{\text{is}}\) varied between 9638 and 11980 MPa R\(^2\) is the proportion of the variance in the dependent variable predictable from the independent variable(s). Stress-strain curves and line of linear regression are depicted in Fig. 12. The linear regression is a linear approach for modelling the relationship between scalars. The slope of the trend line represents the Young modulus, \(E_{\text{is}}(\varepsilon)\) obtained by linear regression.

5.3. Poisson ratio

For evaluating the Poisson ratio, two transducers were placed orthogonally to the load direction and on the opposite cube sides were used for measuring both the transverse and longitudinal strains \(\varepsilon_t,\varepsilon_l\) (see Fig. 13).

---

\(^1\) \(\sigma_1\) denotes the ultimate compressive strength.
5.4. Direct tensile test

Under a direct tensile load test, the shot-earth has shown an elastic-brittle behavior, thus the tensile branch may be well described by a linear constitutive law until the brittle failure according to the classical formula \( \sigma_y(\epsilon) = E_{\text{c}} \epsilon \), being \( E_{\text{c}} \) the elastic modulus of the soil-cement mixture (after curing) and \( \epsilon \) is the axial strain. The direct tensile strength test consists of applying an increasing traction force until complete failure. Under pure traction load, the tensile strength value is measured as the ratio between the applied load and specimen area. The direct tensile strength test provides more representative values than the flexural tests. Three shot-earth cylinders of 150 mm in diameter and 300 mm height, cored from existing walls, were tested under direct traction. The average strength of the specimen was of about 11 MPa. Because of the notch, the middle cross section was reduced by 26%, see Fig. 14.<sup>2</sup> The stress \( \sigma_{et} \) was calculated as the ratio between the applied tensile load and the area of the notched cross section of the specimen. Table 5 summarizes the mechanical properties of the shot-earth obtained from direct tensile tests. The average strength was found to be 1.159 MPa. Two extensometers with a gauge length of 38 mm were set to measure the longitudinal displacements.

The Fig. 15 shows the stress-strain curve of the specimen under direct tensile test.

5.5. Three points flexural test

In measuring the tensile strengths of brittle materials, the direct test method might be difficult to implement, inaccurate and costly [39]. These are the reasons why, when a material is already well known, the indirect tensile test is often used for quality control and characterization purposes. A typical three-point loading bending test [37] set-up is shown in Fig. 16. The maximum bending tensile stress is calculated under the assumption that the neutral axis is at mid-height of the cross-section and the stress distribution is triangular. The modulus of rupture, that is also defined as the bending tensile strength [38], can be measured using the classical formula \( \sigma_{et} = (h/2)M_{\text{max}}/J_4 = 3FL/(2bh^3) \).

<sup>2</sup> The depth of the notch is approximately 10 mm, thus the reduced area of the cross section turns out to be

\[ \pi \times 140^2/4 \approx 13773 \text{ mm}^2 \]
Table 6 summarizes the flexural modulus of rupture of the shot-earth specimens. It should be noted that $\sigma_f$ shows relatively low scattering and it varied between 2.281 and 1.759 MPa. Tensile strengths obtained by indirect tensile test is higher, by a factor of two or more, than those obtained by the conventional direct test [39].

5.6. Evaluation of experimental results

Analyzing the compression stress-strain diagram up to a third of the strength, the behavior of the material can be considered as linearly elastic. At $\sigma_e$ equal to 70% of the maximum compressive strength, the curvature increases rapidly (hardening) and, after achieving the maximum stress, the diagram shows a softening branch until the failure point, as depicted in Fig. 9. A loosening of the internal structure and an increase of the transverse strain is recorded after the stress reaches 0.7 $\sigma_e$.

The tensile strength of soil-cement depends by the test method. The values of the direct tensile strength recorded during this test campaign are coherent with those reported in literature [35]. The ratio between tensile and compressive strengths is about 1 : 8 as shown in Table 7.

In summary it is possible to affirm that the shot-earth tested has the mechanical characteristics of low strength concrete (see Table 7). It is, however, necessary to highlight the fact that the concrete-like behavior of the shot earth must be further confirmed, in order to safely use the RC concrete design practices for calculating the shot earth elements. This could also lead to applying the same strengthening and maintenance strategies used for concrete to shot earth structures [13].

6. Walls

The data of the first test campaign on walls highlighted that the frontally spraying methodology yields the best results and therefore this placing method was retained. Three walls were prepared and tested, two under axial compression and one under diagonal compression.

The two walls tested under compression were designed with the dimension of $800 \times 800 \times 100$ mm$^3$ and one of them was reinforced by a steel mesh in each side. The third wall was manufactured with the dimension of $500 \times 500 \times 110$ mm$^3$ according to ASTM E519/E519M-15, the standard test method for diagonal tension [33].

6.1. Axial compression test of walls

Before testing the walls under compression, the top surface was rectified by a rapid set cement mortar. The load applied to the specimen was distributed with a steel profile placed at the top surface. Linear variable differential transducers (LVDT) with a gauge length of 250 mm were placed on both faces of the specimen for measuring both longitudinal and lateral displacements. The geometry of the supports and disposition of LVDTs are shown in Fig. 17. The axial stress–strain curve (see Fig. 18) for the unreinforced shot-earth wall has shown a linear behavior in the first part and then a progressive decrease in stiffness until the maximum load of about 756 kN was achieved. The modulus of elasticity $E$ equals to about 4418 MPa and it was computed on the range 5% > 30% of $\sigma_e$. In general the wall exhibited a brittle failure in short time after achieving the maximum compressive stress. As de-
Table 1
Experimental tests carried out on specimens.

| Specimen          | Test                               | Regulation             |

|                   | Visual detection of the quality of the material. | UNI EN 12390-1         |
| Wall 0.8 × 0.8 × 0.1 m"³ unreinforced | Compression test on the specimen | –                      |
| Wall 0.8 × 0.8 × 0.1 m"³ reinforced | Compression test on the specimen | –                      |
| Wall 0.5 × 0.5 × 0.11 m"³ reinforced | Diagonal compression test | ASTM E519/ES19M-15     |
| Cube 0.15 × 0.15 × 0.15 m"³ | Compressive strength | UNI EN 12390-1         |
| Prism 0.12 × 0.12 × 0.36 m"³ | Elastic modulus | UNI EN 12390-3         |
|                   |                                    | UNI EN 12390-5         |
| Cube 0.15 × 0.15 × 0.15 m"³ | Poisson ratio | UNI 6133                |
| Prism 0.12 × 0.12 × 0.36 m"³ | Shear strength and modulus | ASTM E519-15           |

Calculated parameters such as the ultimate shear strength τ and the shear modulus G. While shear modulus measurements are considered accurate, the measure of the shear strength is more complex. The presence of non-pure shear loading, non linear behavior, edges, material coupling and presence of normal stresses make questionable the evaluation of the shear strength.

However, according to [33], the shear stress τ can be calculated as

$$\tau = \frac{0.707P}{A},$$

being P is the load applied to the wall and A is the area of the specimen. The shear strain is calculated as follows:

$$\gamma = \frac{\Delta V}{S} = \frac{\Delta h}{g},$$

where γ is the shear strain, ΔV is the vertical shortening, Δh is the horizontal extension and g is the gage length. Accordingly, the shear modulus turns out to be $G = \tau / \gamma$. Fig. 22 displays the shear stress–strain curve of the wall whereas Fig. 23 shows the diagonal deformation during time.

The shear mechanical parameters are listed in Table 9. Assuming an elastic behavior of the material, G was measured between the 5 and 33% of τ. Failure of the specimen was preceded by the appearance and consecutive propagation of a crack that crossed diagonally the specimen as showed in Figs. 24a-b. Just before collapse, a system of running cracks developed, thus causing the complete failure.

7. Conclusion

The shot-earth is a new and sustainable construction material consisting in a mix of excavated soil, sand and water placed by high speed projection (dry process). In this case the shot earth was stabilized in order to improve its mechanical properties. The construction material obtained reveals good mechanical properties, which resemble those of a low-strength concrete. The shot-earth spraying technology is very flexible and adapted to a wide range of non-structural and structural applications such as curved, free-formed and form-resistant structures. The experimental investigation accomplished in this work leads to the following main conclusions:

- Excavated soil can be used as a construction material provided that its characteristics are known and a proper stabilization is used;
- the high-speed projection allows for optimal compaction and homogeneity of the material, provided that the projection is performed frontally on an open mould;
- it might be argued that the mechanical behavior of shot-earth is similar to that of a low strength concrete;
- the stabilization rate and type can be changed in order to fit the specificity of each application of this new material;
- the shot-earth increases the sustainability and circularity of the construction market by using a high rate of excavated soil in field, thus reducing the logistic and the supply of other construction materials.

Further studies are carried out to corroborate the results achieved in the present paper and to investigate other properties such as the shrinkage, creep and durability of this innovative material.

---

3 Recent works concerning the modeling of damage at large deformations can be found in [11,12,14].
4 The mechanical behavior of rammed earth could be improved by inserting fibres into the mixture at the mixing stage. Recent works about cementitious composites reinforced by a steel fabric or discrete fibres can be found in [4,5,17–19,10,15], respectively. Possible applications to improve the building foundations could be investigated too [6].
