PTPN2, a Candidate Gene for Type 1 Diabetes, Modulates Interferon-γ–Induced Pancreatic β-Cell Apoptosis

Fabrice Moore,1 Maikel L. Colli,1 Miriam Cnop,1,2 Mariana Igoillo Esteve,1 Alessandra K. Cardozo,1 Daniel A. Cunha,1 Marco Bugliani,3 Piero Marchetti,3 and Déicio L. Eizirik1

OBJECTIVE—The pathogenesis of type 1 diabetes has a strong genetic component. Genome-wide association scans recently identified novel susceptibility genes including the phosphatases PTPN22 and PTPN2. We hypothesized that PTPN2 plays a direct role in β-cell demise and assessed PTPN2 expression in human islets and rat primary and clonal β-cells, besides evaluating its role in cytokine-induced signaling and β-cell apoptosis.

RESEARCH DESIGN AND METHODS—PTPN2 mRNA and protein expression was evaluated by real-time PCR and Western blot. Small interfering (si)RNAs were used to inhibit the expression of PTPN2 and downstream STAT1 in β-cells, allowing the assessment of cell death after cytokine treatment.

RESULTS—PTPN2 mRNA and protein are expressed in human islets and rat β-cells and upregulated by cytokines. Transfection with PTPN2 siRNAs inhibited basal- and cytokine-induced PTPN2 expression in rat β-cells and dispersed human islet cells. Decreased PTPN2 expression exacerbated interleukin (IL)-1β + interferon (IFN)-γ–induced β-cell apoptosis and turned IFN-γ alone into a proapoptotic signal. Inhibition of PTPN2 amplified IFN-γ–induced STAT1 phosphorylation, whereas double knockdown of both PTPN2 and STAT1 protected β-cells against cytokine-induced apoptosis, suggesting that STAT1 hyperactivation is responsible for the aggravation of cytokine-induced β-cell death in PTPN2-deficient cells.

CONCLUSIONS—We identified a functional role for the type 1 diabetes candidate gene PTPN2 in modulating IFN-γ signal transduction at the β-cell level. PTPN2 regulates cytokine-induced apoptosis and may thereby contribute to the pathogenesis of type 1 diabetes. Diabetes 58:1283–1291, 2009

Type 1 diabetes is a chronic autoimmune disease with a strong genetic etiology. Genetic predisposition to type 1 diabetes depends on a small number of genes having large effects and a larger number of genes having small effects (1). These genes interact with putative environmental factors, which may include viral infections, triggering insulinitis and eventually diabetes (2). Recent genome-wide association studies have shown association between type 1 diabetes and four chromosome regions, pointing to several new candidate genes for the disease (3). Most of the newly and previously identified genes are assumed to regulate immune function. This contrasts with type 2 diabetes, where similar studies indicate a major role for genes regulating β-cell function (4).

We have presently evaluated whether the recently identified candidate genes for type 1 diabetes (3,5) are expressed in pancreatic β-cells and whether their expression is modulated by proinflammatory cytokines. This was done by examining our previous array analyses of cytokine-treated or virus-infected rodent and human β-cells/pancreatic islets (6–10; complete information on these arrays is available at the Beta Cell Gene Expression Bank [11]) and new array analyses performed in our laboratory using the new Affymetrix rat array Genechip 230.2.0 (unpublished data). This analysis identified β-cell expression of the candidate gene protein tyrosine phosphatase (PTP)N2.

PTPN2 (also known as TC-PTP or PTP-S2) is a member of the first nontransmembrane (NT1) subfamily of PTPs. PTPs are a superfamily of enzymes with opposite roles compared with protein tyrosine kinases (12). PTPN2 is expressed in immune cells, and its expression is modulated by cell cycle, mitogenic agents, and cytokines (13). PTPN2 exists as two isoforms generated from alternative splicing: a major TC45 isoform (45 kDa) containing a nuclear localization sequence and that shuttles between the nucleus and the cytoplasm and a less abundant TC48 isoform (48 kDa) that is anchored to the endoplasmic reticulum (13). Many targets have already been identified for TC45, including Janus kinases (JAKs) and signal transducer and activator of transcription (STATs), p42/44 mitogen-activated protein kinase (MAPK) (extracellular signal–related kinase [ERK]), epidermal growth factor receptor (EGFR), and insulin receptor β (IRβ) (14–17). Several of these pathways have been implicated in the control of β-cell physiology, survival, and expansion (18–20).

We have previously suggested that islet inflammation and subsequent β-cell death develops in the context of a “dialogue” between the immune system and β-cells (21). Thus, β-cells exposed to viral agents (6,22), or to endogenous Toll-like receptor ligands (23), release cytokines and chemokines that attract and activate macrophages, T-cells, and B-cells. These immune cells will then trigger β-cell apoptosis via contact mediators such as Fas-FasL and/or via secretion of proinflammatory cytokines such as interferon (IFN)-γ, interleukin (IL)-1β, and tumor necrosis factor (TNF)-α (21,24). IFN-γ has a key role in this process. Thus, neither IL-1β nor TNF-α alone induce
human or rodent β-cell death, but combinations of these cytokines with IFN-γ lead to 50% β-cell death after 6–9 days (21,24). IFN-γ signal transduction involves activation of the tyrosine kinases JAK1 and JAK2 that phosphorylate STAT1, which then dimerizes and translocates to the nucleus where it binds γ-activated sites of diverse genes (21). Excessive activation of JAK/STAT signaling may lead to cell death, and STAT1 transcriptional activity is regulated by multiple negative feedback mechanisms, including inhibition of JAKs by specific phosphatases and by the suppressors of cytokine signaling and inhibition of STAT1 activity by protein inhibitor of activated STAT (PIAS) proteins (25). β-Cells from STAT1-deficient mice (STAT1<sup>−/−</sup>) are protected against IL-1β + IFN-γ-induced apoptosis, and STAT1<sup>−/−</sup> mice are more resistant to diabetes induced by multiple low doses of streptozotocin or after backcross into NOD mice (18,26). This protective effect takes place at the β-cell level, since islets from STAT1<sup>−/−</sup>, but not from wild-type mice, prevent diabetes when transplanted into wild-type mice subsequently treated with multiple low doses of streptozotocin (27). However, it still remains unclear whether modulation of phosphatases modifies IFN-γ-induced β-cell apoptosis.

We presently report that PTPN2 is regulated by the cytokines IL-1β, IFN-γ, and TNF-α in rodent and human pancreatic islet cells. Importantly small interfering (si)RNA-mediated PTPN2 knockdown increases STAT1 activation and aggravates cytokine-induced β-cell apoptosis in a STAT1-dependent manner. These observations indicate that one of the new candidate genes for type 1 diabetes may act at the immune and β-cell level, exacerbating cytokine-induced β-cell apoptosis under inflammatory conditions.

RESEARCH DESIGN AND METHODS

Culture of primary fluorescence-activated cell–sorted rat β-cells, human islets, and INS-1E cells. Male Wistar rats (Charles River Laboratories, Brussels, Belgium) were housed and used according to the guidelines of the Belgian Committee for Care and Use of Animals. Islets were isolated by collagenase digestion and handpicked under a stereomicroscope. β-Cells were purified by autofluorescence-activated cell sorting (FACSARia; BD Bioscience, San Jose, CA) (28,29). The preparations contained 90.4 ± 0.8 kg/m2, transformer was isolated by enzymatic digestion and density-gradient centrifugation of 25<sup>−</sup> cells, and dispersed human islets, respectively. The complexes were diluted five times in antibiotic-free medium and added to the cells at a final concentration of 30 nmol/l siRNA (except when indicated otherwise) for 48 h recovery period and subsequently exposed to cytokines.

Cell treatment and nitric oxide measurement. The following cytokine treatments were used, based on previous dose-response experiments (10,24,30): recombinant human IL-1β (specific activity 1.8 × 10<sup>7</sup> units/mg; a gift from C.W. Reinolds, National Institutes of Health, Bethesda, MD), 10, 50, or 100 nmol/l 3-isobutyl-1-methylxanthine, 5% fetal bovine serum (FBS), 0.5% charcoal-absorbed BSA (Boehringer, Indianapolis, IN), 50 units/ml penicillin, and 50 μg/ml streptomycin (29,30). During cytokine exposure, cells were cultured in the same medium but without serum.

Human islets were isolated from 11 nondiabetic organ donors (age 63 ± 5 years; BMI 25.1 ± 0.8 kg/m<sup>2</sup>) in Pisa, Italy, with the approval of the local ethics committee. Islets were isolated by enzymatic digestion and density-gradient purification (31) and cultured in M199 medium containing 5.5 mmol/l glucose. Their functional status was determined using glucose-stimulated insulin release and was 2.8 ± 0.4 (expressed as stimulation index). The human islets were shipped to Brussels within 1–5 days of isolation. After overnight recovery in Ham’s F-10 medium containing 10 mmol/l glucose, 2 mmol/l glutamax, 50 μmol/l 3-isobutyl-1-methylxanthine, 5% fetal bovine serum (FBS), 0.5% charcoal-absorbed BSA (Boehringer, Indianapolis, IN), 50 units/ml penicillin, and 50 μg/ml streptomycin, islets were exposed to cytokines in the same medium without FBS for 2 days. The percentage of β-cells, examined in the 11 dispersed islet preparations by staining with anti-insulin antibody (1,11,000; Sigma, Bornem, Belgium) and donkey anti-mouse IgG rhodamine (1:200; Lucron Bioproducts, De Pinte, Belgium), was 49 ± 5%.

The rat insulin-producing INS-1E cell line (a gift from Dr. C. Wollheim, Centre Medical Universitaire, Geneva, Switzerland) was cultured as previously described (32,33). mRNA extraction and real-time PCR. Poly(A)<sup>+</sup> mRNA was isolated from INS-1E cells, rat primary β-cells, and human islets using the Dynabeads mRNA DIRECT kit (Invitrogen) and reverse transcribed as previously described (10,29,37). The real-time PCR amplification was done as described (29,37), using SYBR Green and compared with a standard curve (38). Expression values were corrected for the housekeeping gene glyceroldehyde-3-phosphate dehydrogenase (GAPDH). IL-1β alone does not modify GAPDH expression, whereas exposure to IL-1β + IFN-γ reduces its expression according to cell death in INS-1E cells (Supplementary Fig. A1 and 10,27,10). The primers used in this study are detailed in Supplementary Table A2 (online appendix).

Western blot analysis. Cells were washed with cold PBS and lysed with either Laemmli buffer or phospho lysis buffer (the compositions of the buffers are provided in Supplementary Table A5). Lysates were then resolved by 8–10% SDS-PAGE and transferred to a nitrocellulose membrane. The antibodies used in this study are listed in Supplementary Table A4. Immunoreactive bands were visualized using the SuperSignal West Femto chemiluminescent substrate (Thermo Scientific), detected using a LAS-3000 charge-coupled device camera and quantified with the Aida Analysis software (FujiFilm).

Immunofluorescence. INS-1E cells were seeded onto glass coverslips and treated as indicated. Cells were washed with cold PBS, fixed for 10 min in 100% methanol at −20°C, washed three times with PBS, quenched 5 min in PBS/0.1% sodium borohydride, washed twice with PBS, and incubated for 5 min in PBS containing 0.2% Triton X-100 (PBST). After a 1-h blocking with 5% normal goat serum in PBST, cells were incubated overnight with PTPN2 antibodies (0.7 μg/ml) in PBST/0.5% normal goat serum (Supplementary Table A4). Cells were washed three times with PBST, and FITC-conjugated goat anti-rabbit antibody (1:200) was added. Cells were washed twice with PBST, and mounted in mounting medium (Dakocytomation), and immunofluorescence was visualized on a Zeiss microscope.
We first evaluated the expression of PTPN2 mRNA (both TC45 and TC48 isoforms) in primary fluorescence-activated cell–sorted rat β-cells, human islets, and INS-1E cells.

**RESULTS**

**Cytokines upregulate PTPN2 mRNA and protein expression in primary rat β-cells, human islets, and INS-1E cells.** We first evaluated the expression of PTPN2 mRNA (both TC45 and TC48 isoforms) in primary fluorescence-activated cell–sorted rat β-cells, human islets, and rat insulin–producing INS-1E cells and tested whether cytokine treatment would affect its expression. PTPN2 mRNA was expressed in untreated primary rat β-cells and human islets cells, and IL-1β + IFN-γ exposure upregulated its expression by 9.6-fold (rat β-cells) and 2.2-fold (human islets) after 24 and 48 h, respectively (Fig. 1A and B). A time course of IL-1β + IFN-γ treatment in INS-1E cells indicated that PTPN2 mRNA was already induced after 2 h, increasing progressively up to 24 h (Fig. 1C). We then confirmed by Western blot that PTPN2 was upregulated by two- and threefold, respectively, in human islets and INS-1E cells after IL-1β + IFN-γ treatment (Fig. 1D and E).

In accordance with previous reports (13), we observed TC45 (arrow, Figs. 1D and 3B) to be the major PTPN2 isoform expressed in β-cells, with TC48 being poorly expressed (Fig. 1D and 3B). In contrast, the expression of PTPN22 (another phosphatase associated with type 1 diabetes risk; 39) was only present in samples from rat spleen and lymph nodes (used as positive controls), whereas no or marginal PTPN22 expression was observed in primary β-cells, human islets, and INS-1E cells. The expression of PTPN22 was not modified by cytokines (Supplementary Fig. A2 in the online appendix).

**PTPN2 subcellular distribution.** PTPN2 was mainly located in the nucleus under unstimulated conditions (Fig. 2, left panels). However, a 15-min treatment with IFN-γ alone or in combination with IL-1β or TNF-α resulted in redistribution of the protein between the cytoplasm and the nucleus (Fig. 2, middle and right panels).

**siRNA targeting PTPN2 inhibits basal and cytokine-induced PTPN2 expression and exacerbates cytokine-induced apoptosis in INS-1E cells, primary rat β-cells, and dispersed human islets.** To this end, INS-1E cells were left untransfected, transfected with an irrelevant control siRNA (siCtrl), or with an siRNA targeting both PTPN2 isoforms (siPTPN2). Cells were then left untransfected, or treated for 24 h with IL-1β, IFN-γ, TNF-α, or with the combination of IL-1β + IFN-γ or TNF-α + IFN-γ. PTPN2 mRNA expression was significantly upregulated after IL-1β and IL-1β + IFN-γ treatment in untransfected and siCtrl-transfected INS-1E cells (Fig. 3A). The expression of PTPN2 proteins was increased by all cytokines tested, alone or in combination, in both untransfected and siCtrl-transfected cells (Fig. 3B and C), suggesting that PTPN2 expression is regulated at both transcriptional and post-transcriptional levels. Transfection with PTPN2 siRNA potently inhibited basal and cytokine-induced PTPN2 expression at the mRNA and protein level (Fig. 3A–C). We then evaluated whether siRNA-mediated PTPN2 inhibition affects cytokine-induced apoptosis in INS-1E cells.

**Statistical analysis.** Data are presented as means ± SE. Comparisons were performed by two-tailed paired Student’s t test or by ANOVA followed by Student’s t test with Bonferroni correction. A P value < 0.05 was considered statistically significant.
PTPN2 REGulates cytoKINE-IndUCed β-cELL deATH

FIG. 2. Effects of cytokine exposure on PTPN2 subcellular distribution. INS-1E cells were plated onto glass coverslips and left untreated or treated for 15 min with IFN-γ (100 units/ml), IL-1β (10 units/ml) + IFN-γ (100 units/ml), or TNF-α (1,000 units/ml) + IFN-γ (100 units/ml). Cells were then fixed and processed for immunofluorescence as described in Research Design and Methods. The figure is representative of five independent experiments. (A high-quality digital representation of this figure is available in the online issue.)

PTPN2 inhibition increases IFN-γ-induced STAT1 and STAT3 phosphorylation. Taking into account that STAT1 is a substrate of PTPN2 in other cell types (13) and that it is an important mediator of cytokine-induced β-cell apoptosis (18), we next examined the effect of PTPN2 inhibition on the kinetics and magnitude of IFN-γ-induced STAT1 phosphorylation. STAT1 phosphorylation was highly induced after 15 min of IFN-γ treatment in both untransfected and siCtrl-transfected controls, slowly decreasing between 2 and 24 h (Fig. 5A and B). However, IFN-γ-induced STAT1 phosphorylation was markedly enhanced in cells lacking PTPN2, reaching a peak at 1–2 h and slowly decreasing afterward (Fig. 5A and B). We confirmed that the increased STAT1 phosphorylation in PTPN2-deficient cells was not due to an augmentation of total STAT1 content in these cells (Fig. 5A). Comparable results were observed for STAT3, another target of PTPN2 phosphatase activity, with clearly increased STAT3 phosphorylation in PTPN2-deficient cells (Fig. 5A and C). These data demonstrate that the phosphatase PTPN2 is a major modulator of IFN-γ-induced STAT1 and STAT3 activity in β-cells. We also evaluated the p42/44 MAPK (ERK), EGFR, and IRβ activation pathways, previously described as PTPN2 targets in other cell types (14,16,40). Neither ERK nor EGFR signaling pathways were affected after PTPN2 inhibition in INS-1E cells (Supplementary Fig. A5). On the other hand, there was an increase in IRβ phosphorylation after 30 min of cytokine treatment in PTPN2-inhibited INS-1E cells that lasted until 14 h (Supplementary Fig. A5).

Double knockdown of PTPN2 and STAT1 protects INS-1E cells against cytokine-induced apoptosis. To evaluate the role of STAT1 in the exacerbation of cytokine-induced β-cell apoptosis observed after PTPN2 inhibition, we additionally interfered with STAT1 in a double knockdown approach. We first confirmed by Western blot that both PTPN2 and STAT1 siRNAs adequately inhibited their respective targets without affecting the expression of the other protein and also that the double transfection of PTPN2 and STAT1 siRNAs potently inhibited both target proteins (Fig. 6A). As previously shown (Fig. 4), IL-1β + IFN-γ or TNF-α + IFN-γ induced apoptosis to a similar degree in both control conditions, and PTPN2 inhibition exacerbated cytokine-induced apoptosis, also rendering treatment with IFN-γ alone toxic to the cells (Fig. 6B).
Inhibition of STAT1 protected the cells against IL-1β + IFN-γ and TNF-α + IFN-γ–induced apoptosis (by 56 and 67%, respectively). STAT1 knockdown abrogated the proapoptotic effect of PTPN2 inhibition in cells exposed to IFN-γ or to combinations of cytokines (Fig. 6B). These results were confirmed using a second siRNA targeting PTPN2 expression (Supplementary Fig. A6) and suggest that increased STAT1 activity contributes to the aggravation of cytokine-induced apoptosis in PTPN2–deficient β-cells.

**DISCUSSION**

We presently show that the phosphatase PTPN2 is expressed in human islets and rat primary and immortal β-cells and that its expression is regulated by the proinflammatory cytokines IL-1β, IFN-γ, and TNF-α in these cells. PTPN2 was first identified in humans as a T-cell PTP (41) with two spliced variants, namely TC45 and TC48 (13,42). In rat β-cells and human islets, the TC45 isoform is by far the most prevalent (Fig. 1D and 3B), and it is able to shuttle between the nucleus and the cytoplasm after cytokine exposure (Fig. 2). This change in subcellular location of PTPN2 has been shown previously in other cell types (14,16) and allows the phosphatase to target numerous cellular substrates, including cytoplasmic JAK tyrosine kinases, EGFR, the IRβ and nuclear STAT1, STAT3, STAT5, and STAT6 (43,44). Because of its modulatory role in a wide variety of signaling pathways, perturbations in PTPN2 expression are associated with diverse pathogenic processes, including ABC-like diffuse large B-cell lymphomas (45), inflammation-associated tumorigenesis (44), and several autoimmune disorders (see below).

PTPN2 inhibition in β-cells results in an early and more intense STAT1 and STAT3 activation after IFN-γ treatment, suggesting that this phosphatase plays an important role in the dephosphorylation and consequent inactivation of these transcription factors in β-cells. This early regulation of IFN-γ–induced STAT1 activation seems to be critical for the subsequent triggering of β-cell apoptosis, since PTPN2–deficient β-cells show an aggravation of cytokine-induced apoptosis, which is reverted by the combined inhibition of PTPN2 and STAT1. Importantly, PTPN2 inhibition unmasked the proapoptotic effect of IFN-γ alone in both INS-1E and primary β-cells, while it failed to augment palmitate- or CPA-induced β-cell death. Taken together, these observations indicate two interesting aspects that require additional investigation: 1) The crucial negative feedback of PTPN2 on the STAT1 signaling pathway suggests that PTPN2 is part of the “defense mechanisms” triggered by β-cells in response to cytokines. It remains to be clarified why this and other defense mechanisms (24) are not sufficient to protect β-cells against apoptosis. 2) IFN-γ alone induces STAT1 activation, but this only leads to apoptosis when PTPN2 activa-
tion is prevented. This suggests that STAT1 must cross a "nuclear activation threshold" before becoming proapoptotic to H9252-cells. It remains to be clarified whether this threshold depends on the intensity/length and/or periodicity of STAT1 activation, as previously suggested for nuclear factor H9260B (33).

The exacerbation of apoptosis in H9252-cells with decreased PTPN2 expression is independent of augmented NO production. This contrasts with observations reporting that PTPN2-deficient macrophages produce higher amounts of nitric oxide under inflammatory conditions (40,46), highlighting the differential regulation of inflammation-associated genes in cells from different backgrounds.

As discussed above, the transcription factor STAT1 has a major role in cytokine-induced H9252-cell apoptosis in vitro (18) and in vivo (27). It is thus conceivable that a genetically determined modification in the expression and/or the function of PTPN2 may sensitize H9252-cells to IFN-γ-STAT1–driven proapoptotic signaling, amplifying H9252-cell loss under inflammatory conditions, and in some cases, contributing to diabetes. The potential effect of the transient hyper-

FIG. 4. siRNA-mediated PTPN2 inhibition exacerbates cytokine-induced apoptosis in INS-1E cells, primary rat β-cells, and dispersed human islets, independently of NO production. INS-1E cells were transfected and treated as described in Fig. 3. Apoptosis was evaluated after 24 h using HO/PI staining (A) and a Cell Death Detection ELISAnplus kit (B). C: INS-1E cells were transfected and treated as described in Fig. 3, and nitrite concentrations in supernatants were measured as described in RESEARCH DESIGN AND METHODS (D). Primary fluorescence-activated cell–sorted rat β-cells were cultured for 2 days and then transfected as described in Fig. 3. After 2 days of recovery, cells were left untreated (NT) or treated for 72 h with IFN-γ (100 units/ml), IL-1β (10 units/ml) + IFN-γ (100 units/ml), or TNF-α (1,000 units/ml) + IFN-γ (100 units/ml). E and F: Dispersed human islets were left untransfected, or transfected with 30 nmol/l of siCtrl or human siPTPN2 #1 or #2 and cultured for a 48-h recovery period. Cells were then treated with IL-1β (50 units/ml) + IFN-γ (1,000 units/ml) for 48 h when PTPN2 and α-tubulin were evaluated by Western blot (E) and 96 h when apoptosis was evaluated by HO/PI staining (F). Results are means ± SE of four experiments; a: P < 0.001 and b: P < 0.05 vs. untreated NT or untreated transfected with the same siRNA; c: P < 0.001 vs. IFN-γ–treated NT and siCtrl; d: P < 0.001 and e: P < 0.05 vs. IL-1β + INF-γ–treated NT and siCtrl, f: P < 0.001 and g: P < 0.05 vs. TNF-α + INF-γ–treated NT and siCtrl; ANOVA followed by Student’s t test with Bonferroni correction.
phosphorylation of STAT3 or IRβ in PTPN2-inhibited cells remains to be clarified. STAT3 has been reported to be dispensable for -cell development and function (47), but it is generally associated with increased survival of tumoral cells (48), whereas the insulin receptor may exert positive feedback on -cell function and survival (20).

Over the past few years, several new candidate genes have been identified in human type 1 diabetes. Most of these genes are expressed in the immune system, including major histocompatibility complex (e.g., HLA-DRB1), CTLA4, IL-2Rα (CD25), IFIH1 (MDA5), and several protein tyrosine phosphatases, namely PTPN22, PTPN11, and the recently reported PTPN2 (3,49). Modified function or regulation of these genes could contribute to the development of an autoimmune response. Thus, nonsynonymous single-nucleotide polymorphisms (SNPs) in PTPN22 (human LYP) have been associated with type 1 diabetes and other autoimmune processes, probably secondary to defective deletion of autoreactive T-cells during thymic selection (39). The fact that PTPN22 is not expressed in -cells (present data) reinforces the likelihood that this is solely due to effects on the immune system. PTPN2-null mice present severe abnormalities in the immune system, resulting in a systemic inflammatory disease and widespread tissue infiltration by mononuclear cells (13,46,50). Moreover, the PTPN2 gene is associated with several other autoimmune disorders besides type 1 diabetes, including Crohn’s disease, ulcerative colitis, and rheumatoid arthritis (49,51,52). It is currently unknown whether the SNPs identified in the PTPN2 gene on chromosome 18p11 will lead to a gain or a loss of function of the protein. PTPN2 overexpression in other cell types has been shown to induce a p53- and caspase 1–dependent apoptosis (53), whereas suppression of PTPN2 sensitizes -cells to cytokine-induced apoptosis (present data). In experiments on INS-1E cells, we observed that DNA vector–based overexpression of PTPN2 induced 30–50% of apoptosis 36 h after transfection, whereas there was <8% apoptotic cells in control-transfected cells (data not shown). These preliminary results require experimental confirmation in primary rat and human -cells using adenoviral vectors to overex-

FIG. 5. PTPN2 inhibition increases IFN-γ–induced STAT1 and STAT3 phosphorylation. INS-1E cells were left untransfected (NT) or transfected with 30 nmol/l of either a control siRNA (siCtrl) or with a pool of siRNAs targeting PTPN2 (siPTPN2). After 2 days of recovery, cells were left untreated or treated with IFN-γ (100 units/ml) for 15 min, 30 min, 1 h, 2 h, 4 h, 8 h, and 24 h. A: phospho-STAT1, total STAT1, phospho-STAT3, total STAT3, PTPN2, and α-tubulin proteins were evaluated by Western blot. These results are representative of five independent experiments. B and C: Mean optical density measurements of phospho-STAT1 (B) and phospho-STAT3 (C) Western blots corrected for protein loading by α-tubulin. Results are means ± SE of five independent experiments; **P < 0.01 and ***P < 0.001 vs. NT and siCtrl at the same time point, ANOVA followed by Student’s t test with Bonferroni correction.
press PTPN2, but they suggest that PTPN2 must be tightly regulated to avoid deleterious effects.

Pancreatic β-cells themselves may play an active role in the pathogenesis of type 1 diabetes (21), and at least three of the type 1 diabetes–associated genes are expressed in β-cells, namely insulin, IFIH1 (MDA5) (6,54), and PTPN2 (present study). β-Cells have been shown to participate actively in the recruitment and activation of the immune system by secreting various chemokines and cytokines under inflammatory conditions (18,21,55) and by providing “danger signals” to the immune system during apoptosis, especially in the context of local inflammation (56). We presently demonstrate that changes in PTPN2 function in β-cells sensitize these cells to surrounding proapoptotic inflammatory signals (e.g., cytokines), potentially amplifying β-cell loss and insulitis. This suggests that PTPN2, a type 1 diabetes–associated gene, may modulate β-cell apoptosis in early type 1 diabetes independently of its potential effects on the immune system.
