Abstract. The present study aimed to establish an efficient system for bovine embryo production by \textit{in vitro} fertilization (IVF) that can achieve stable normal fertilization and blastocyst developmental rates in any bull without optimization of the sperm concentration in IVF medium. We examined the effects of a PHE mixture (20 μM D-penicillamine, 10 μM hypotaurine and 1 μM epinephrine), theophylline (2.5 mM), and sperm concentration (1, 2 or 5 × 10$^6$ cells/ml) on fertilization and blastocyst developmental rates. High cleavage rates (78.3 to 92.4%) and blastocyst developmental rates (31.9 to 62.0%) at day 7 were obtained in the presence of PHE and theophylline in IVF medium with a sperm concentration of 2 × 10$^6$ cells/ml using sperm from 9 bulls. In addition, the synergistic effect of PHE and theophylline on normal fertilization (2 pronuclei) was clarified at 12 h after IVF with a sperm concentration of 1 × 10$^6$ cells/ml. Moreover, high linearity, high flagellar beat cross frequency, and low amplitude of lateral head of motile sperm were found by computer-assisted sperm analysis. In conclusion, the combination of the PHE mixture and theophylline synergistically accelerates sperm motility and sperm penetration of bovine oocytes. Theophylline activates sperm motility with increasing intracellular cAMP. However, PHE prevents an excessive increase of cAMP and maintains sperm motility without hyperactivation. When the combination of PHE and theophylline is added to IVF medium at a sperm concentration of 2 × 10$^6$ cells/ml, we can achieve stable normal fertilization and blastocyst development in any bull.

Key words: computer-assisted sperm analysis (CASA), \textit{In vitro} fertilization (IVF), Oocyte, PHE, Theophylline

\cite{J. Reprod. Dev. 61: 99–105, 2015}
cells/ml recovered by a Percoll gradient (45 and 90%) procedure. However, in the case of IVF with a low dose of sperm, such as sex-sorted sperm (2.1 × 10⁶ cells/straw) [19], the number of motile sperm might be insufficient for an IVF protocol using medium supplemented only with theophylline. In a previous study, we reported that the combination of PHE and theophylline resulted in high normal fertilization, cleavage, and blastocyst rates (84.6, 81.1, and 51.6%, respectively) for bovine IVF using 2 × 10⁶ cells/ml of sperm [20]. However, in our previous report [20], we used sperm derived from only one bull. Also the effect of the combination of a PHE mixture and theophylline on fertilization was not examined in detail.

In the present study, to establish an efficient system for bovine embryo production by IVF without optimization of the sperm concentration for sperm derived from any bull, we examined the effects of a PHE mixture, theophylline, and sperm concentration (1, 2 or 5 × 10⁶ cells/ml) on fertilization, cleavage, and blastocyst development. In addition, we evaluated the effects of the PHE mixture and theophylline on sperm motility and the intracellular cAMP concentration of spermatozoa.

Materials and Methods

In vitro maturation and fertilization

IVM of bovine oocytes was performed as described previously [17]. In brief, cumulus-oocyte complexes (COCs) aspirated from follicles (2 to 8 mm in diameter) of slaughterhouse-derived ovaries were cultured for 22 h in a droplet (about 10 COCs/50 μl) of maturation medium under a humidified atmosphere of 5% CO₂ in air at 39 C. The maturation medium consisted of HEPES-buffered TC-199 (Invitrogen, Grand Island, NY, USA) supplemented with 10% fetal calf serum (FCS) (Invitrogen), 0.2 mM sodium pyruvate, 0.02 units/ml follicle-stimulating hormone (from porcine pituitary), 1 μg/ml estradiol-17β and 50 μg/ml gentamicin sulfate. IVF was conducted according to a procedure described previously [21]. Briefly, after the thawing of frozen semen from 9 bulls (A to I), motile sperm were separated using a Percoll (GE Healthcare, Buckinghamshire, UK) gradient (45 and 90%). Matured COCs were co-incubated with motile sperm in droplets (10–13 COCs/100 μl) of modified Brackett and Oliphant (mBO) isotonic medium [21] containing 3 mg/ml fatty acid-free BSA and supplemented with 2.5 mM theophylline and/or PHE (20 μM D-penicillamine, 10 μM hypotaurine and 1 μM epinephrine) [8] at 39 C under a humidified atmosphere of 5% CO₂, 5% O₂ and 90% N₂. All culture droplets were covered with paraffin oil (Nacalai Tesque, Kyoto, Japan). The final sperm concentration (1, 2, or 5 × 10⁶ cells/ml), co-incubation time (12 or 18 h), and treatment with PHE and theophylline are described in the experimental design.

Examination of spermatozoon penetration and in vitro culture of presumptive zygotes after IVF

In vitro culture (IVC) of presumptive zygotes was performed using procedures that were basically the same as described previously [21]. After co-incubation with sperm, zygotes were freed from cumulus cells by vortexing. To evaluate sperm penetration, presumptive zygotes of each experiment group were fixed with ethanol:acetic acid at a ratio of 3:1 and stained with 1% aceto-orcein solution as described previously [22]. Oocytes having an enlarged sperm head(s) or male pronucleus(ei) were defined as penetrated by sperm, and the following categories of oocytes penetrated by sperm were recorded: 1) oocytes with male and female pronuclei with a corresponding sperm tail (2PN), 2) oocytes with more than two enlarged sperm heads or male pronuclei (polyspermy), and 3) oocytes other than 2PN and polyspermy, such as oocytes with an enlarged sperm head and anaphase II/ telophase II chromosome or female pronucleus, or oocytes with a male pronucleus and telophase II chromosome (others). To evaluate the rates of development to blastocysts, cumulus-free presumptive zygotes were cultured for 150 h in droplets (25–30 presumptive zygotes/30 or 40 μl) using modified synthetic oviduct fluid, which contained 1 mM glutamine, 12 essential amino acids for basal medium Eagle, 7 nonessential amino acids for minimum essential medium and 10 μg/ml insulin and was supplemented with 5 mM glycine, 5 mM taurine and 1 mM glucose [21], and 3 mg/ml fatty acid-free BSA instead of polyvinyl alcohol at 39 C under a humidified atmosphere of 5% CO₂, 5% O₂ and 90% N₂. Cleavage and blastocyst rates were assessed after 30 h and 150 h of IVC, respectively. All embryos that developed to blastocysts were subjected to counting of their cell numbers using an air-drying method [22].

Evaluation of sperm motility and sperm motility parameters by CASA

Motile sperm separated using a Percoll gradient (45 and 90%) and recovered motile sperm were incubated in 100-μl droplets of IVF medium (final concentration of 10 × 10⁶ cells/ml in 100-μl droplets) at 39 C in 5% CO₂, 5% O₂ and 90% N₂. After incubation, 3 μl of IVF medium from droplets was placed onto 4-chamber slides with a depth of 20 μm (Art. No. SC 20-01-04-B, Leja, Nieuw-vennep, Netherlands) on a micro warm plate (Kitazato, Shizuoka, Japan) at 37 C for counting. Sperm in three fields (at least 100 spermatozoa) in a chamber were divided into motile and dead sperm, and the percentages of motile sperm and sperm motility parameters were evaluated using a CASA system (SMAS, DITECT, Tokyo, Japan). The evaluated sperm motility parameters were straight line velocity (VSL), curvilinear velocity (VCL), average path velocity (VAP), linearity (LIN = VSL/VCL × 100), flagellar beat cross frequency (BCF) and amplitude of lateral head (ALH).

Evaluation of intracellular cAMP concentration of spermatozoa

The intracellular cAMP concentration of sperm was measured using the CAMP Biotrak enzyme immunoassay system kit (RPN2251, Amersham, GE Healthcare, Life Sciences, UK) according to the protocol provided by the manufacturer. The microplate contained 12 × 8-well strips coated with donkey anti-rabbit IgG. In brief, motile sperm recovered using a Percoll gradient (45 and 90%) were incubated in 400 μl of IVF medium (final concentration of 10 × 10⁶ cells/ml) in a 1.5-ml tube for 2 h at 39 C under 5% CO₂, 5% O₂ and 90% N₂. After incubation, each aliquot was centrifuged at 500 × g for 5 min, and the supernatant was removed. The sperm pellet was resuspended in 200 μl of lysis buffer and mixed on a microplate shaker for 10
min at room temperature. One hundred microliters of lysate and 100 μl of antiserum were added to the wells and incubated at 4 C for 2 h. After incubation, 100 μl of cAMP-peroxidase conjugate was added to each well and incubated at 4 C for 1 h. All supernatant was aspirated, and all wells washed four times with 400 μl of wash buffer using a microplate washer (Model 1575, Immunowash™, Bio-Rad Laboratories, Tokyo, Japan). One hundred and fifty microliters of enzyme substrate was added to all wells and mixed on a microplate shaker at room temperature for 1 h. One hundred microliters of 1.0 M sulfuric acid was added to each well, the optical density was determined with a plate reader (iMark™, Bio-Rad Laboratories) at 450 nm, and cAMP concentrations in each well were evaluated.

Experimental design

In experiment 1, to examine the effect of the PHE mixture and different sperm concentrations on sperm penetration and blastocyst development rates in sperm derived from various bulls, IVF medium containing theophylline was used. Some of the matured COCs were co-incubated with sperm derived from bulls A, B, and C at a concentration of 1, 2 or 5 × 10⁶ cells/ml for 18 h, and fertilization status was examined. Other presumptive zygotes were cultured, and cleavage and blastocyst development were examined. As controls for sperm penetration and blastocyst development, oocytes incubated at a sperm concentration of 5 × 10⁶ cells/ml supplemented only with theophylline were used. In addition, to confirm blastocyst development after IVF using a sperm concentration of 2 × 10⁶ cells/ml in IVF medium containing a combination of theophylline and PHE, presumptive zygotes fertilized with sperm from six bulls (D to I) were cultured.

In experiment 2, to examine the effect of the PHE mixture and theophylline on sperm fertilizability in detail, matured COCs were co-incubated with sperm at a concentration of 1 × 10⁶ cells/ml (bulls A and I) for 12 h in IVF medium with or without PHE and/ or theophylline. Sperm of bull A showed similar 2PN rates among sperm concentrations of 1, 2, 4 and 5 × 10⁶ cells/ml for 18 h of IVF, irrespective of PHE and theophylline addition, in experiment 1. In addition, to confirm the effect of the PHE mixture and theophylline on sperm activity, after incubation (0, 2, 4, 6, and 8 h) of sperm of bull I, sperm motility was evaluated by CASA. For evaluation of sperm motility parameters, motile sperm with a VSL of ≥ 25 μm/sec (50.49 to 75.32%) were selected, as it has been recognized that motile sperm having a VSL of less than 25 μm/sec (25.51 to 40.51%) are probably not related to fertilization (Fig. 1).

To examine the effect of PHE and theophylline on the intracellular cAMP concentration of spermatozoa (bull I), the intracellular cAMP concentration of sperm was evaluated after 2 h of incubation in IVF medium with or without PHE and theophylline. As a control, sperm immediately after Percoll treatment (0 h) were used. All experiments in each group were carried with at least 3 replicates.

Statistical analysis

Sperm penetration rates (total penetration, 2PN, and polyspermy rates) were compared among groups by Chi-square test. The percentages of cleavage and development to blastocysts, mean cell numbers in blastocysts, average sperm motility parameters, and the concentration of intracellular cAMP after 2 h of incubation were compared by one-way ANOVA followed by Tukey-Kramer’s HSD test as a post hoc test. Intracellular cAMP concentrations at 0 and 2 h in each treatment were compared by Dunnett’s test. All analyses were performed using JMP Pro (version 10.0.2, SAS Institute, Cary, NC, USA).

Results

Experiment 1

The effects of PHE and sperm concentrations on penetration are shown in Table 1. In bull A, the 2PN rates were similar among different sperm concentrations (1, 2 and 5 × 10⁶ cells/ml), irrespective of PHE addition. In bulls B and C at a sperm concentration of 1 × 10⁶ cells/ml without PHE, the total penetration and 2PN rates were the lowest among all experimental groups. In bull C, at a sperm concentration of 1 × 10⁶ cells/ml with the PHE mixture, the total penetration rate was significantly lower than that of the control (sperm concentration of 5 × 10⁶ cells/ml without PHE; P < 0.05). In all bulls, the highest polyspermy rates were observed when PHE was added to IVF medium including theophylline at a sperm concentration of 5 × 10⁶ cells/ml.

The effects of PHE and different sperm concentrations on embryonic development are shown in Table 2. At sperm concentrations of 1 and 2 × 10⁶ cells/ml (bulls A, B, and C), there were no significant differences in cleavage rate, blastocyst rate and mean cell number in blastocysts compared with those at 5 × 10⁶ cells/ml without PHE (control). However, in bull C, the cleavage rate at a sperm concentrations of 1 × 10⁶ cells/ml tended to be lower (P = 0.08) than those at 2 × 10⁶ cells/ml in the control. In addition, the mean cell numbers of blastocysts at a sperm concentration of 1 × 10⁶ cells/ml tended to be lower (P = 0.13) than those at 2 × 10⁶ cells/ml and in the control in bull C. As shown in Table 3, after fertilization with a sperm concentration of 2 × 10⁶ cells/ml in the presence of PHE and theophylline, cleavage rates of 78.3 to 92.4% and blastocyst development rates of 31.9 to 62.0% were obtained from 6 bulls (D to I).

Experiment 2

In bulls A and I, after 12 h of co-incubation of COCs and sperm (1 × 10⁶ cells/ml), the total penetration and 2PN rates in the presence of PHE and theophylline were higher than those in the other experimental groups (Table 4; P < 0.05). The effects of PHE and

Values are means ± SD. Embryos derived from bulls D to F and bulls G to I were cultured in 40-μl and 30-μl droplets, respectively.
theophylline on sperm motility and sperm motility parameters are shown in Fig. 2. The total percentage of motile sperm decreased with increasing incubation period in all experimental groups; in particular, those at 6 and 8 h with only theophylline supplementation were significantly lower than those in the nontreatment (Fig. 2A; P < 0.05). On the other hand, in terms of the percentages of sperm moving at more than 25 µm/sec in the VSL, only PHE addition showed stable motility (~70%) during the experimental period, with low variation compared with the percentages in the nontreatment, theophylline addition, and combination of PHE and theophylline groups (Fig. 2B). The average VAP levels of sperm incubated with theophylline regardless of PHE addition were significantly increased at 2 h and decreased at 6 h compared with those in the nontreatment group (Fig. 2C; P < 0.05). Regardless of PHE addition to IVF medium, the average LIN at 2 h with theophylline was significantly higher than those in the nontreatment group and the PHE addition only group (Fig. 2D; P < 0.05). The average BCF with PHE and theophylline at 6 h was higher than those in the nontreatment group and the PHE addition only group (Fig. 2E; P < 0.05). The average ALH levels at 6 and 8 h with PHE and theophylline were significantly lower than those in the nontreatment group and the PHE addition only group (Fig. 2F; P < 0.05).

As shown in Fig. 3, the mean intracellular cAMP concentration of sperm incubated with theophylline (167.5 ± 54.5 fmol/5 × 10^6 cells; mean ± SD) at 2 h was significantly higher than for those incubated with PHE (53.9 ± 54.7 fmol/5 × 10^6 cells) and in the nontreatment group (45.1 ± 47.9 fmol/5 × 10^6 cells; P < 0.05). However, the cAMP concentration of sperm incubated with PHE and theophylline (117.3 ± 92.9 fmol/5 × 10^6 cells) showed an intermediate value between those of sperm incubated with theophylline or PHE. The mean intracellular cAMP concentration of sperm incubated with theophylline only showed a significantly higher value than that at 0 h (68.2 ± 19.9 fmol/5 × 10^6 cells; P < 0.05).

**Discussion**

In bull A, addition of PHE to the IVF medium at different sperm concentrations (1, 2, and 5 × 10^6 cells/ml) did not affect 2PN rates at

<sup>a, b, c</sup> Values with different letters within each bull differ significantly (P < 0.05). *Others: an enlarged sperm head with an anaphase II/telophase II chromosome or a male pronucleus was observed. 2PN, two pronuclei; poly, penetrated with more than two sperm.

---

**Fig. 2.** The sperm motility and sperm motility parameters during incubation in IVF medium supplemented with or without PHE mixture and theophylline. A: % of total motile sperm; B: % of motile sperm with a VSL of ≥ 25 µm/sec; C: mean VAP (µm/sec); D: mean LIN (%); E: mean BCF (Hz); F: mean ALH (µm). Values in panels C to F were calculated by using sperm that showed a VSL of ≥ 25 µm/sec. <sup>a,b,c</sup> Values with different letters differ significantly (P < 0.05). The error bar indicates the SEM. Nontreatment, mBO medium only; PHE, mixture of D-penicillamine, hypotaurine, and epinephrine; Theo, theophylline. VSL, straight line velocity; VAP, average path velocity; LIN, linearity (VSL/VCL [curvilinear velocity] × 100); BCF, flagellar beat cross frequency; ALH, amplitude of lateral head.
the percentage of total motile sperm became lower than that of the nontreatment group after 6 h of incubation; however, addition of PHE to the IVF medium with theophylline prevented the decrease in the percentage of total motile sperm. Sperm incubated in IVF medium with only PHE maintained a stable percentage (about 70%) of motile sperm with a VSL of ≥ 25 μm/sec based on total sperm during the 8 h incubation period. We speculated that the addition of PHE to IVF medium maintains sperm motility. The averages of VAP and LIN at 2 h were increased in the presence of theophylline regardless of PHE addition compared with those in the nontreatment group. These results indicate that theophylline enhanced the progressive motility of sperm within a short period.

In the presence of PHE and theophylline at 6 h after incubation, average BCF was significantly higher compared with that in the nontreatment group. On the other hand, the average ALH of sperm incubated with the combination of PHE and theophylline at 6 and 8 h was significantly lower than that in the nontreatment group. This result is not consistent with a previous report describing that ejaculated sperm incubated in Tyrode’s HEPES-buffered medium with heparin showed significantly high average ALH and BCF levels at 1 h to 4 h compared with those incubated in Tyrode’s HEPES-buffered medium without heparin supplementation [23]. Chamberland et al. [23] suggested that the increases in BCF and ALH of sperm incubated with heparin in vitro could be related to the hyperactivation of sperm [23]. In addition, theophylline induced hyperactivation and the acrosome reaction in sperm of dogs [24] and enhanced the rate of sperm penetration into oocytes in humans [25]. The increase in BCF and decrease in ALH observed in the present study probably indicate that sperm incubated with PHE and theophylline acquire a high level of activity without hyperactivation.

It was previously reported that adenosine and catecholamine agonists might increase cAMP in the cytoplasm of sperm and accelerate the beating of flagella related to BCF in mice [12]. In the present study, theophylline, one of the PDE inhibitors, increased intracellular cAMP. In humans, pentoxifylline, another PDE inhibitor, also increased the intracellular cAMP content of sperm in a manner correlated to increases of BCF and ALH [26]. However, in the present study, the ALH of sperm incubated with PHE and theophylline at 6 and 8 h was suppressed compared with that of sperm incubated with only theophylline. Because sperm incubated with PHE and theophylline at 2 h showed a relatively low intracellular cAMP concentration compared with that of sperm incubated with only theophylline addition, we speculated that PHE activated an unknown signaling pathway to prevent the increase in intracellular cAMP and subsequently maintained sperm motility.

According to these hypotheses, sperm incubated with PHE and theophylline maintain high progressive motility. Therefore, these sperm have increased opportunities to encounter oocytes and subsequently penetrate them. Further study is needed to clarify the relationship between sperm motility parameters, intracellular cAMP content of sperm and not only IVF medium including theophylline and PHE mixtures, but also D-penicillamine, hypotaurine, and epinephrine separately.

In conclusion, the combination of a PHE mixture and theophylline synergistically accelerates sperm motility and sperm penetration of bovine oocytes. Theophylline activates sperm motility with increasing
in intracellular cAMP. However, PHE prevents an excessive increase in cAMP and maintains sperm motility without hyperactivation. When the combination of PHE and theophylline is added to IVF medium at a sperm concentration of $2 \times 10^6$ cells/ml, we can obtain stable normal fertilization and blastocyst development rates using sperm from any bull.

Acknowledgments

This study was supported by a Grant-in-Aid for Scientific Research from the Japan Society for the Promotion of Science to M. Nagano (No. 25450441). We thank the Genetics Hokkaido Association for the donation of frozen bull sperm.
