Abstract

Introduction: Biological sex has a paramount influence on the pathophysiology of diseases, and thus on clinical presentation. In this study, we provide a comprehensive analysis of sex-specific differences in patients with myocarditis. Materials and Methods: Patients with myocarditis who were admitted to our study center in the time-period of 2009–2019 were retrospectively enrolled in this study. Clinical data, laboratory parameters, and measurements from transthoracic echocardiography were extracted from hospital records. Follow-up was acquired for 2 years after admission. Results: Two hundred twenty-four patients with myocarditis were enrolled in this study. Of these, 78% were men and 22% women. Female patients were older (median 50 years vs. 35 years, \( p < 0.0001 \)), had a higher prevalence of respiratory tract infections, and had less frequently ST-segment elevations on electrocardiogram (ECG) (28% vs. 59%, \( p = 0.003 \)). Furthermore, C-reactive protein was lower in women (median 0.60 mg/dL vs. 3.90 mg/dL, \( p < 0.0001 \)), but showed a less pronounced decrease within 3 days when compared to men (fold-change 1.00 vs. 0.80, \( p = 0.002 \)). Cardiac magnetic resonance imaging was conducted less often in women, whereas time to coronary angiography was significantly longer. We found no difference in left ventricular systolic function or all-cause-mortality between the 2 sexes. Conclusion: We observed sex-specific differences in laboratory parameters, abnormalities on ECG, and diagnostic procedures conducted in patients with myocarditis. Understanding these differences, both at the cellular level and in regard to the clinical presentation of patients, could be helpful in the diagnosis and treatment of this disease, and could further expand our understanding of its pathophysiology.

Introduction

The term “myocarditis” refers to inflammatory reactions within the myocardium, which are most frequently a result of preceding infections with cardiotropic viruses. Interestingly, while old age was identified as a risk factor for several other cardiovascular diseases, this does not particularly apply to myocarditis. In contrast, previous studies identified male sex as a pivotal risk factor for the development of myocarditis, with an estimated male to female ratio of 3:1 in affected patients [1, 2].

In contrast to “gender identity,” which refers to the extent of a person’s identification with masculinity, femininity, and the spectrum in between [3], “biological sex” is determined by the expression of genes of an individual’s sex chromosomes (X and Y chromosomes). The expression of these genes results in differing concentrations of sex hormones, which in turn results in differential development of internal and external sexual organs, cardiovascular physiology, and even differences in cellular biology between biological men and women [2].

Due to the increasing understanding of pathophysiology, the possible influence of biological sex on the development and presentation of diseases has gained increasing scientific attention and recognition in recent years. However, while sex-specific differences have been thoroughly investigated in cardiovascular diseases like coronary artery disease or heart failure [4–7], the impact of biological sex on the presentation and outcomes of patients with myocarditis was relatively less well addressed by previous studies. In a large retrospective study involving 27,129 hospitalizations for myocarditis, Shah et al. [8] recently reported that female patients had a higher risk of in-hospital complications than males, and female gender was identified as an independent risk predictor for inhospital mortality in myocarditis. Furthermore, another study found that female patients with myocarditis presented with dyspnea rather than with chest pain and that plasma levels of creatinine kinase (CK) were significantly higher in the male subgroup. However, the authors of the latter study did not find any other sex-specific differences in laboratory parameters, probably due to the low number of patients enrolled in their study [9].

Biological sex has a considerable influence on several intra- and intercellular processes, and thus on the development and progression of several disease entities [10, 11]. To the best of our knowledge, there is currently no evidence regarding sex-specific differences in inflammatory parameters, such as C-reactive protein (CRP), leukocyte count, or neutrophil-to-lymphocyte ratio (NLR) in patients with myocarditis. Furthermore, studies investigating the sex-specific impact on echocardiographic changes after acute myocarditis are also not available. Our study aimed to study differences between men and women because they could provide additional information on the pathophysiology of the disease and could aid in the sex-specific adaption of diagnosis and treatment.

Materials and Methods

The study protocol was reviewed and approved by the Ethics Committee of the State of Salzburg, Austria (EK Nr: 1181/2020). The study was conducted according to the principles of Good Clinical Practice and the Declaration of Helsinki.

A database search of all consecutive patients admitted to the University Hospital of Salzburg, Austria, in the time-period of 2009–2019 was conducted. Patients with myocarditis were identified through a search on discharge diagnoses recorded in hospital discharge forms, which were classified according to the International Classification of Diseases, Tenth Revision (ICD-10) diagnostic codes (I40.0, I40.1, I40.8, I40.9, and I51.4). The presence of acute myocarditis, as defined by the current recommendations of the European Society of Cardiology [12], was confirmed by revision of all clinical records. Admissions for elective procedures or follow-up visits were excluded from the study. Clinical and laboratory data were extracted from the hospital records and discharge letters of enrolled patients. Laboratory data of the day of presentation and after 3 days of treatment were analyzed. Data from trans-thoracic echocardiography (TTE) and electrocardiogram (ECG) were acquired from the 1st available set of data after presentation, that is, from the emergency department, the intensive care unit, or the hospital ward. Data on follow-up TTE were acquired from exams conducted within 3–6 months after the initial presentation. Follow-up on mortality was acquired for 2 years after presentation; death was defined as that from any cause within 2 years after the index hospitalization. The classification of histopathological findings was graded according to the Dallas criteria [13], whereas findings of magnetic resonance imaging (MRI) were graded according to the Lake Louise criteria [14].

Statistical analyses were performed with SPSS (version 22.0, SPSS Inc., Chicago, IL, USA) and R (version 4.0.2., R Core Team [2013], R Foundation for Statistical Computing, Vienna, Austria; http://www.R-project.org/). Data distribution, skew, and kurtosis of continuous data were assessed visually and by performing a Shapiro-Wilk test. Since data were not normally distributed, median ± interquartile range (IQR) are depicted and medians were compared using a Mann-Whitney U test. Categorical data were analyzed by applying Fisher’s exact test. A p value of <0.05 was considered statistically significant.

Results

Baseline Characteristics

A total of 224 patients were enrolled in this study. Of these, 78% (n = 174) were men and 22% (n = 50) were...

IQR, interquartile range; BMI, body mass index; ECG, electrocardiogram; TTE, transthoracic echocardiography; LV, left ventricular; CAD, coronary artery disease; EF, ejection fraction.
women. Female patients were significantly older than males (median 50 years [IQR 36–62] versus median 35 years [IQR 24–45], \( p < 0.0001 \)) and had a higher prevalence of cerebral artery disease as known comorbidity (4% vs. 0%, \( p = 0.049 \), see Table 1).

Although there was no sex-specific difference in the frequency of infections occurring 4–6 weeks before admission to the hospital (males \([m]\): 68%, females \([f]\): 59%, \( p = 0.305 \)), female patients who had an infection prior to myocarditis had a significantly higher prevalence of respiratory tract infections and lesser gastrointestinal infections than males (respiratory tract: 69% vs. 40%; gastrointestinal: 7% vs. 23%, \( p = 0.029 \)). Despite a high prevalence of infections prior to myocarditis, we neither observed seasonal clustering nor sex-specific differences in this regard (Table 1).

**Vital Signs, ECG, and TTE**

At presentation, there was no statistically significant difference in blood pressure, heart frequency, peripheral oxygen saturation, or body temperature between men and women. In the ECG, female patients had significantly less frequent ST-segment elevations (28% vs. 59%, \( p = 0.003 \)); upon TTE, females had a significantly smaller left ventricular (LV) end-diastolic diameter (median 44 mm vs. median 48 mm, see Table 1) than male patients. There was no difference in LV systolic function between men and women.

**Laboratory Findings**

In the initial laboratory exam at presentation, women had significantly lower plasma levels of CRP (median 0.60 mg/dL vs. median 3.90 mg/dL, \( p < 0.0001 \)) and CK (median 97.5 IU/L vs. 211.0 IU/L, \( p < 0.0001 \)) than men. Furthermore, bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), LDH, and hemoglobin were lower, whereas the thrombocyte count was higher than that in male patients (Table 2). Despite a higher CRP at the initial laboratory exam, men had a higher fold-change (FC) and delta (\( \Delta \)) of CRP after 3 days than women (FC CRP 0.80 vs. 1.00, \( p = 0.002 \), see Table 2; Fig. 1). Furthermore, serum levels of CK showed a more pronounced decline after 3 days than those in the female patients (\( \Delta \) CK −87.0 IU/L vs. −30.0 IU/L, \( p = 0.029 \), see Table 2). It is important to note that we did not observe sex-specific differences in the NLR, eosinophil-to-lymphocyte ratio, basophil-to-lymphocyte ratio, or monocyte-to-lymphocyte ratio but observed a statistically insignificant trend toward higher plasma concentrations of high-sensitivity troponin in men (median 179 ng/L vs. median 73 ng/L, \( p = 0.101 \)).

**Diagnostic Procedures and Outcome**

Within 24 months of the index hospitalization, 4 patients died, resulting in an all-cause mortality rate of 2.8%. We did not observe a statistically significant difference in all-cause mortality between the 2 sexes; however, our study might have been underpowered in this regard.

In the total cohort, 95 patients (42%) underwent coronary angiography, 27 patients (12%) coronary computed tomography, and 3 patients (1%) myocardial scintigraphy. Cardiac MRI was conducted in 166 patients (74%), whereas endomyocardial biopsy was performed in 17 patients (8%). In women, MRI was conducted significantly less often (61% vs. 79%, \( p = 0.015 \)), whereas endomyocardial biopsy was performed significantly more often (16% vs. 5%, \( p = 0.019 \), see Table 3). In females who underwent coronary angiography, the time from admission to procedure was significantly longer than that in male patients (median 2 days vs. median 0 days, \( p = 0.001 \), see Table 3).

Furthermore, we did not observe a statistically significant difference in \( \Delta \) or FC of ejection fraction when compared to follow-up TTE at 3–6 months after the index hospitalization (see Table 3). Regarding the findings of MRI, we observed a slightly higher yet statistically insignificant prevalence of myocardial edema (57.1% vs. 46.8%, \( p = 0.457 \)) in women. Furthermore, the location of inflammatory infiltrates was more evenly distributed than that in men, in whom a trend toward a predominance of lateral myocardial segments was observed (\( p = 0.273 \); see online suppl. Table 1; for all online suppl. material, see www.karger.com/doi/10.1159/000520870).
There were no statistically significant differences in the findings of endomyocardial biopsy between both sexes, probably because of the low number of procedures conducted.

### Discussion

Current evidence suggests that biological sex has a paramount influence on cellular processes, and thus on the development and progression of several disease entities [2, 11]. Previous studies identified male sex as a risk factor for the development of myocarditis, whereas female sex was associated with worse outcomes in affected patients [1, 8]. Although these findings suggest that biological sex plays a pivotal role during the course of myocarditis, previous evidence on this aspect is limited. Therefore, we aimed to provide a comprehensive analysis of sex-specific differences of baseline characteristics, vital signs, abnormalities in the ECG and TTE, as well as of laboratory findings, diagnostic procedures, and outcomes of patients presenting with acute myocarditis. Interestingly,

| Table 2. Laboratory findings in male and female patients with myocarditis |

IQR, interquartile range; eGFR, estimated glomerular filtration rate; AST, aspartate transaminase; ALT, alanine transaminase; CK-MB, creatinine kinase myocardial band; FC, fold-change; hsTnT, high-sensitivity troponin; pBNP, Pro-brain natriuretic peptide; Δ, delta; IL-6, interleukin 6; NLR, neutrophil-to-lymphocyte ratio; ELR, eosinophil-to-lymphocyte ratio; BLR, basophil-to-lymphocyte ratio; MLR, monocyte-to-lymphocyte ratio.
we found that plasma levels of CRP at baseline were significantly lower in women; however, men showed a higher FC of CRP, indicating a more pronounced decrease in inflammatory parameters within 3 days of admission to the hospital. Furthermore, cardiac MRI was conducted less often in women, and the time from admission to coronary angiography was significantly longer. Hence, biological sex affects not only cellular processes and pathophysiology but probably also the clinical management of patients with myocarditis.

Some sex-specific differences in patients with myocarditis have been reported previously. For example, male sex is more prevalent among patients with myocarditis, and females tend to be older [1]. Furthermore, a recent study by Patriki et al. [9] demonstrated that plasma levels of CK were higher in male patients with myocarditis than those of CK in the biological females. The same observation was also made in our study cohort, but additionally, we found statistically significant differences in CRP, bilirubin, AST, ALT, LDH, hemoglobin, and thrombocyte count between the 2 sexes. While sex-specific differences in bilirubin, AST, ALT, LDH, hemoglobin, and thrombocyte count are well known [15–17] and supposedly independent of the presence of myocarditis, the difference in CRP in our study cohort is of special interest. Female patients in our study had significantly lower plasma concentrations of CRP at baseline (median 0.6 mg/dL vs. 3.9 mg/dL, \( p < 0.0001 \)), but they showed a less pronounced decrease in CRP within 3 days after admission to the hospital, as assessed by \( \Delta \) and FC of CRP (FC 1.00 vs. 0.80, \( p = 0.002 \)). Furthermore, we observed a trend toward higher levels of interleukin 6 and NLR in women, which, however, remained statistically insignificant (interleukin 6: median 54.3 pg/mL vs. median 27.7 pg/mL, \( p = 0.990 \); NLR: 3.39 vs. 2.20, \( p = 0.465 \)), probably because our study was underpowered in this regard. Nevertheless, taken together, these findings could indicate that the inflammatory process in acute myocarditis differs between men and women, which is also underlined by statistically insignificant trends toward the higher prevalence of myocardial edema and differently affected myocardial segments in women. In this regard, the fact that we observed significantly more respiratory tract infections and less gastrointestinal tract infections 4–6 weeks prior to myocarditis in biological women might also refer to immunological differences between men and women. In fact, previous studies found that biological sex has a marked influence on the immune system and its response to pathogens and autoantigens, which also becomes apparent with the increased risk for autoimmune diseases such as systemic lupus erythematosus or autoimmune thyroid disease in women [18, 19]. In inflammatory processes, sex hormones have been reported to elicit diverging effects, with male androgens eliciting predominantly anti-inflamm-
logical sex can also bias clinical reasoning and decision-making. For example, since coronary artery disease is generally more prevalent in men [31] and men had a higher prevalence of ST-segment elevations in our study cohort, the significantly shorter time to coronary angiography in male patients could be a result of the attending physicians’ priority to rapidly rule out myocardial ischemia in men in contrast to women. Similarly, the lower utilization of cardiac MRI in women was also observed in the study by Younis et al. [30], and could be a result of the often atypical clinical presentation of female patients, which could have had an impact on the clinical decisions made by physicians. Nevertheless, our study was conducted at a single study center, and these findings need to be confirmed by large multi-center studies in the future.

Our study has several limitations. First, because of the low prevalence of myocarditis, we chose a retrospective study design to test our hypotheses. Due to the low level of evidence of this design, however, a prospective multicenter study would have been preferable. Second, data from follow-up TTE were only available from 49 patients, and a possible selection bias cannot be excluded (i.e., patients with echocardiographic abnormalities during the index hospitalization could have been examined earlier than those with a normal exam). Large prospective multicenter studies should address this issue further. Last, in contrast to previous studies [8], we did not observe sex-specific differences in mortality. However, our study was probably underpowered to detect these differences, and therefore, prospective trials are warranted.

In summary, we observed sex-specific differences in laboratory parameters, abnormalities on ECG, and diagnostic procedures conducted in patients with myocarditis. While biological sex has a known influence on cellular processes and thus on pathophysiology of diseases, several sex-specific differences are related to diagnostic procedures and can probably be attributed to differences in clinical management. Understanding these differences, both at the cellular level and in regard to the clinical presentation of patients, could be helpful in the diagnosis and treatment of this disease, and could further expand our understanding of its pathophysiology.

Conclusions

In patients with myocarditis, sex-specific differences can be observed in laboratory parameters, abnormalities on the ECG, and diagnostic procedures conducted. As such, female patients had lower plasma concentrations of CRP at baseline but showed a less pronounced decrease within 3
days after admission. Furthermore, cardiac MRI was conducted less often in women, whereas time to coronary angiography was significantly longer. Understanding these differences, both at the cellular level and in regard to the clinical presentation of patients, could be helpful in the diagnosis and treatment of this disease, and could further expand our understanding of its pathophysiology.

**Statement of Ethics**

The study was conducted according to the principles of Good Clinical Practice and the Declaration of Helsinki. Informed consent was not obtained since it was a retrospective study. The study protocol was reviewed and approved by the Ethical Review Board of the state of Salzburg, Austria (EK Nr: 1181/2020), prior to data collection.

**Conflict of Interest Statement**

The authors declare that there is no conflict of interest regarding the publication of this article.
