ABSTRACT

Thermally-pulsating AGB stars provide three-fourths of the matter returned to the interstellar medium. The mass and chemical composition of their ejecta largely control the chemical evolution of galaxies. Yet, both the mass loss process and the gas chemical composition remain poorly understood. We present maps of the extended 12CO and 13CO emissions in IRC+10216, the envelope of CW Leo, the high mass loss star closest to the Sun. IRC+10216 is nearly spherical and expands radially with a velocity of 14.5 km/s. The observations were made On-the-Fly with the IRAM 30-m telescope; their sensitivity, calibration, and angular resolution are far higher than all previous studies. The telescope resolution at λ = 1.3 mm (11′′ HPBW) corresponds to an expansion time of 500 yr. The CO emission consists of a centrally peaked pedestal and a series of bright, nearly spherical shells. It peaks on CW Leo and remains relatively strong up to rphot = 180′′. Further out the emission becomes very weak and vanishes as CO gets photodissociated. As CO is the best tracer of the gas up to rphot, the maps show the mass loss history in the last 8000 yr. The bright CO shells denote over-dense regions. They show that the mass loss process is highly variable on timescales of hundreds of years. The new data, however, confirm previous claims of a strong decrease of the average mass loss in the last few thousand years. The over-dense shells are not perfectly concentric and extend farther to the N-NW. The typical shell separation is 800–1000 yr in the middle of the envelope, but seems to increase outwards. The shell-intershell brightness contrast is ≥3. All those key features can be accounted for if CW Leo has a companion star with a period ≃ 800 yr that increases the mass loss rate when it comes close to periastron. Higher angular resolution observations are needed to fully resolve the dense shells and measure the density contrast. The latter plays an essential role in our understanding of the envelope chemistry.

Key words. astrochemistry — stars: AGB and post-AGB — circumstellar matter — stars: individual (IRC +10216)

1. Introduction

The mass and chemical composition of stellar ejecta are keys to our understanding of Galactic chemical evolution. The main source of ejecta are Supernova explosions and AGB star winds. The latter, in particular, the winds of thermally pulsing AGB (TP-AGB) stars, provide as much as three-quarters of the matter returned to the interstellar medium (ISM) (Gehrz, 1989). During their phase of high mass loss, the envelopes become opaque at optical and near-IR wavelengths; their hot, innermost parts are then best studied in the mid- and far-IR and their cool outer parts at millimeter wavelengths.

IRC+10216, the thick dusty envelope of CW Leo and the TP-AGB star closest to the Sun, is a choice target for these studies. Its C-rich nature was pointed out by Herbig & Zappala ([1970]) who assigned a cool N type for the star (C9.5). Besides its proximity (≃ 130 pc), IRC+10216 is remarkable in several respects: a large mass (≃ 2M⊙) and apparent size (6′), a nearly spherical shape and constant expansion velocity, except near the star, and, last but not least, an incredible wealth of molecular species: half of the known interstellar species are observed in its C-rich outer envelope. These molecules range from CO, the main tracer of the cool molecular gas and other diatomic and triatomic species (see e.g. Cernicharo et al., 2000; 2010), to refractory element molecules (Cernicharo & Guélin, 1987), the last detected molecule being HMgNC (Cabezas et al., 2013), to long carbon chains species CnH (Cernicharo et al., 1996; Guélin et al., 1997 and references therein), and include all known interstellar anions (C3N, H+, n=2,3,4 and Cn+1N+, n=0,1,2, 3; Thaddeus et al., 2008; Cernicharo et al., 2008 and references therein).

In addition to this large list of molecules expected in a carbon-rich environment, oxygen-bearing species such as H2O (Melnick et al., 2001), OH, and H2CO (Ford et al., 2003; 2004) have been also detected. While the presence of H2O and H2CO in more evolved C-rich protoplanetary nebula can be easily explained through photochemical processes (Cernicharo, 2004), their presence in IRC+10216, a star still in the AGB phase, is particularly difficult to explain. Agúndez et al. (2010) have shown that an important parameter for the chemical models is the spatial structure of the gas in the circumstellar envelope (CSE) which, if clumpy enough, could permit the interstellar UV radiation to penetrate into the inner zones of the CSE and trigger a chemistry out of thermodynamical equilibrium.

Although at low angular resolution the mm-wave dust and CO emissions of IRC+10216 appear fairly smooth and spherically symmetric, high resolution V-light images of the envelope (Crabtree et al., 1987; Mauro & Huggins, 1999; 2000; Leao et al., 2006), and emission maps of reactive molecular species
Fig. 1. **Top left box:** Velocity-integrated CO (J=2-1) line emission in the central 400′×400′ area (V_{LSR} range from -41 to -12 km s^{−1}).

**Other upper maps:** Velocity-channel maps (resolution 2 km s^{−1}); marked velocities are relative to the LSR systemic star velocity (V_*=−26.5 km s^{−1}); the units of the color scale correspond to K km s^{−1}. Positive and negative velocities correspond to the rear and front parts of the envelope, respectively.

**Bottom right panels:** Observed ^{12}CO(2-1) line profiles along a strip to the east for Δδ=0″; the upper left numbers indicate Δα in arcseconds and the upper right numbers the intensity scaling factor applied to plot all spectra at the same T^{*}_A scale (in K). The contribution of the telescope error beam has been removed from the data and is shown in red for each spectrum.

**Bottom-left panel:** the ^{13}CO (2-1) line emission integrated between V_{LSR} -28.5 and -24.5 km s^{−1} (black contours) superimposed on the ^{12}CO emission in the same velocity range. Note that the r = 50″ shell also appears in ^{13}CO. The inner shells are not resolved by the 11″ beam.
1993). Emission from reactive species is weaker at PA = +20° and −160° (Lucas et al., 1995), suggesting that CW Leo may be leaving the AGB and is developing a bipolar outflow that sweeps away parts of the slowly expending spherical envelope. Further evidence of matter ejection along the same strip at the declination of the star (Δδ = 0°′′), Red line: the response of the telescope error beam to the 12CO(2-1) emission along the same strip. The error beam consists of 3 Gaussians of FWHM 65″′, 250″′, and 860″′ and intensities 1.9 10−3, 3.5 10−4, and 2.2 10−5 relative to the main beam, respectively. Blue line: The 12CO(2-1) line intensity after removal of the error beam response.

More recently, Decin et al. (2011) reported Herschel/PACS maps of the dust FIR emission showing that the dusty shells observed in V-light extend in the envelope up to radii R ≥ 3′. Although it was known, from low-resolution studies, that CO emission extends at least as far, little was known so far about the gas distribution at such radii, more particularly in the region where CO is photodissociated by interstellar (IS) UV radiation. Moreover, contrary to dust, CO yields the velocity information needed to reconstruct the 3-D envelope structure. Fong et al. (2003), who mapped the emission up to R = 150″′ with BIMA (13″ synthesized beam), reported the presence of a number of arc-shaped features apparently associated with the thin dust shells reported by Mauron & Huggins (2000). However, the limited size and low sensitivity of the BIMA map prevented them from drawing an image of the full envelope. To derive the molecular gas distribution up to at least 4′ from the star and investigate CW Leo’s mass loss history over the last 10 5 years, we have observed with high sensitivity the 12CO and 13CO J = 1-0 and 2-1 line emissions throughout the envelope, using the HERA focal plane array receiver on the IRAM 30-m telescope. The HPBW of the telescope, 11″, or 1400 AU, is small enough to resolve clumps of gas expelled with a 500 yr delay.

2. Observations

The main observations of 12CO and 13CO J=2-1 (see Figure 1) were carried out in February 2009 with the HERA 9-pixel, dual-polarization receiver on the IRAM 30-m telescope. Further observations of 12CO and 13CO J=1-0 and 2-1 were made between 2011 and 2012, using the Eight Mixter Receiver (EMIR): E90 and E230 single-pixel dual polarization receivers. The astronomical signals are expressed in the $T_A^*$, scale (antenna temperature corrected for spillover losses and atmospheric opacity) in Figures 1 and 2, and in the $T_{MB}$ scale in the subsequence figures ($T_{MB} = T_A^*/B_{eff}$, where $B_{eff}$, the telescope beam efficiency is 0.79, 0.78, 0.61, and 0.59 at 110 GHz, 115 GHz, 220 GHz, and 230 GHz, respectively; Kramer et al. (2013). The atmospheric opacity was measured from the comparison of the sky emissivity, recorded every five minutes, to that of hot and cold loads using the ATM code (Cernicharo, 1985). The zenith sky opacity was typically 0.1-0.2. The spectral data were processed by an autocorrelator consisting of 461 channels spaced by 312 KHz (0.41 km s−1 at 230.5 GHz).

The nine sky-channels of HERA of each linear polarization were successively tuned to the frequencies of J=2-1 12CO and J=2-1 13CO lines. The receivers operated in single sideband mode, with image rejections ≥ 10 dB. The observations were made in the On-The-Fly mode by mapping nine partly overlapping areas of size 240″′ × 240″′. Each map consisted in constant declination scans, separated in declination by 4″′ (for the central map) or 6″′ (for the other maps). The scanning velocity was 8″′ per second and the data dumped every 0.15 seconds, yielding one spectrum every 1.2″′ in RA. The observing time per individual map was ≃1 h.

The first map was centred at 0.0, i.e. on the star CW Leo, maps 2-5 at (+240″′,0″′) (-240″′,0″′) (0″′,+240″′) and (0″′,-240″′). Maps 6-9, of size 120″′×120″′, were centred at (+180″′,+180″′) (+180″′,-180″′) (-180″′,+180″′), and (-180″′,-180″′). The combined map fully samples a square area of size 480″′×480″′, centred on the star. Four additional 240″′×240″′ areas, centred on the four corners of the square and extending up to 720″′ from the star, were also observed.

Prior to observing each individual map, the pointing and focus of the telescope were checked on the quasar OJ287. In addition, a small mini-map centred on the star, was observed with HERA in the position switching mode for further checks of calibration and pointing. The coordinates adopted for position (0,0) are α2000=09h 47m 57.3s, δ2000=13° 16′ 43.3″. The telescope half-power beamwidth (HPBW) was 11″ and 22″, respectively.
for the $^{12}$CO J=2-1 and J=1-0 lines, and 11.5" and 23" for the $^{13}$CO J=2-1 and J=1-0 lines.

The relative positions of the $9 \times 2$ sky-channels of HERA were measured on the first (0,0) map. There, the star and its surroundings appear in CO emission as a bright compact source. We found shifts of up to 2" from the nominal channel positions. We measured the relative calibration of the $9 \times 2$ channels of HERA; differences of up to 20% were found. The shifts and correction factors were applied and the data re-sampled on a common grid with $\Delta \alpha = \Delta \delta = 2\arcsec$ before merging the different sky and polarization channels into a single map. The r.m.s noise per 0.4 km s$^{-1}$-wide channel, after averaging overlapping maps and both polarizations over a grid with points separated every 2", varies between 0.14 K in the central positions and 0.06 K at the map borders ($\pm 240\arcsec, \pm 240\arcsec$).

The EMIR observations consisted of a partial map of $^{13}$CO $J = 1 - 0$ emission, and of deep integrations of $^{12}$CO $J = 2 - 1, 1 - 0$ along selected strips. The EMIR $^{13}$CO $J = 2 - 1$ and $^{12}$CO $J = 1 - 0$ data were observed in the raster mode and consisted of maps of $120 \times 120\arcsec$ and of strips extending up to $\pm 720\arcsec$ from the star (reference position was 15 arcmin west from the star). The typical r.m.s noise per channel of 0.4 km s$^{-1}$ is 0.06 K). These data are used in section 3.1 to derive the gas physical properties through the envelope.

The 30-m telescope response to point sources is not restricted to a Gaussian beam with (FWHP of 11"), but includes near side-lobes and an error beam. The latter has been measured at 230 GHz and at 115 GHz and contains 25% and 14%, respectively, of the energy collected by the telescope, and extends over the entire IRC+10216 envelope. At 230 GHz, it can be approximated by 3 Gaussians with FWHP of 65", 250", and 860" ($Kramer et al., 2013$). The signals observed at position (0,0) are then significantly affected by the response of the error beam to the outer envelope and those observed in the outer envelope are affected by the compact central source. Since our map fully covers the bulk of the envelope CO emission (whose diameter is $\leq 400\arcsec$), we were able to correct the response of the error beam in every velocity-channel at each observed position. The error-beam corrected velocity-channel maps are shown in Figure 1 for the central $400\arcsec \times 400\arcsec$ region. The maps prior to error-beam correction may be found in the appendix of the electronic version of this paper. Figure 2 shows the $^{12}$CO(2-1) intensities prior to and after this correction along a cut at the declination of the central star. The contribution of the error beam at the frequencies of the J=1-0 lines of $^{12}$CO and $^{13}$CO is much less important as this beam is weaker and broader, and has not been removed from the data.

Finally, Figure 3 shows the central frame of a video (online) showing the spatial distribution of the CO emission at different velocities. The CO data have been resampled to a velocity resolution of 0.1 km s$^{-1}$, and hence, there is a significant correlation between consecutive frames in the online video.

### 3. Results and discussion

Given that the outer envelope is in expansion with a constant velocity of 14.5 km s$^{-1}$, each velocity-channel map of Figures 1 and 2 delineates a conical sector (of opening $\theta$ and thickness $\delta \theta$), whose axis is aligned with the line of sight to the star CW Leo. The extreme velocities correspond to the approaching and receding polar cones and caps, while the middle velocity ($v = V_{LSR} - V_\star = 0$ km s$^{-1}$, where $V_\star$ is the star LSR velocity, $V_\star = -26.5$ km s$^{-1}$) corresponds to a cut through the star in the plane of the sky.

#### 3.1. Mass loss history

We may estimate the masses of the envelope from the line brightness of key molecules in three different ways.

1) The first method focuses on lines from molecules formed in the upper atmosphere of the star: CO, HCC, HCN (Cernicharo et al., 1996b; Fonfría et al., 2008). The initial abundances of those “parent” molecules, $x_0$, can be estimated from thermochemical equilibrium calculations (see e.g. Agúndez et al., 2010). In C-rich envelopes, the abundance of CO is close to that of oxygen and remains stable up to the CO photodisociation region (see below). Agúndez et al. (2012) analysed
the shapes and intensities of many CO rotational lines, arising from widely different energy levels, using parametrized models of the inner envelope and a radiative transfer code. They assumed spherical symmetry and used the LVG approximation.

For \( x_0 = \text{CO}/\text{H}_2 = 6 \times 10^{-4} \), these authors derived the physical conditions in the inner envelope. Their density profile for \( r < 10^6 \) yields an average mass loss rate \( M_r \approx 2 \times 10^{-7} M_\odot \) for the last 500 yr.

II) The second method relies on the measurement of the CO photodissociation radius, \( r_{\text{phot}} \), defined as the radius where the CO abundance has decreased by a factor of 2: \( x(\text{CO}) = x_0/2 \) (see e.g. Morris & Jura, 1983; Mamont et al., 1988; Stanek et al., 1995; Doty et al., 1995; Schoer & Olofsson, 2001). It assumes that the surrounding interstellar (IS) UV field is known. Most authors adopt the IS radiation field of Jura (1974), which yields in the absence of shielding a CO photodissociation rate of \( G_\text{phot} = 2 \times 10^6 \, \text{s}^{-1} \) (see Table 1 of Mamont et al., 1988). The method also assumes that the gas density decreases as \( r^{-2} \) in the outermost envelope layers and is not too clumpy. Figure 1 shows that the CO(2-1) emission extends up to \( r \approx 180'' \) (or 3.6 \( \text{10}^{17} \, \text{cm} \)) and becomes vanishingly small afterwards. Adopting this radius for the photodissociation radius \( r_{\text{phot}} \), we find a mass loss rate \( M_r \approx 2 \times 10^{-7} M_\odot \) (see Table 3 of Mamont et al., 1988). Obviously, this method yields the average mass loss rate at times \( t > t_0 = r_{\text{phot}}/v_{\text{exp}}, \) i.e. more than 8 \( \text{10}^5 \) yr ago.

III) The last method is based on 13CO. It assumes that, for \( r < r_{\text{phot}} \), the 12CO and 13CO fractional abundances remain constant and close to their nominal values near the star, \( x_0 \). This is expected since the CO molecule is chemically stable because 12CO efficiently self-shields against photodissociation and partially shields 13CO, and because both species are partially shielded by H2. As a matter of fact, the photodissociation radii of both isotopologues are similar (Mamont et al., 1988). As for 13C fractionation, it should be inefficient in IRC+10216 since, contrary to PNe (e.g. CRL618, Pardo & Cernicharo 2007) and detached envelopes (e.g. RScu, Vlemmings et al., 2013), the degree of ionization is known to be low in this envelope (see Mamont et al., 1988, for a discussion of CO shielding, isotopic fractionation, and selective photodissociation in dense CSEs). Finally, the chances that thermal pulses have changed the 13CO/12CO ratio during the last 8000 years are low (Nollett et al., 2003). Hence, the 13CO/12CO abundance ratio is expected to remain constant within \( r_{\text{phot}} \) and close to the elemental 13C/12C ratio. Molecular line observations do point towards a single value 13CO/12CO = 1.6 \( \pm \) 0.3, which is lower than the 13C/12C ratio between the inner and the outer parts of the IRC+10216 envelope (Kahane et al., 1988; Cernicharo et al., 1991, 2000). From the 12CO abundance derived through method (I) above, \( x_0(\text{CO}) = 6 \times 10^{-4} \), we derive a 13CO fractional abundance \( x(\text{13CO}) = 1.3 \times 10^{-5} \).

The physical conditions and molecular column densities can then be derived in the outer envelope by comparing the 12CO, 13CO (2-1), and (1-0) line intensities. Within the range of mass loss rates expected, 12CO should be optically thick and the 13CO lines optically thin (see below). We note that since we are not resolving the smallest structures with our 11'' beam, we choose to evaluate the 12CO and H2 column densities from the optically thin 13C line intensities and the 13CO/12CO ratio quoted above, rather than derive the latter ratio from the optically thick 12CO line intensities and the fitted gas volume densities.

Figure 1 shows the line profiles observed between \( r = 0 \) and \( r = 130'' \) along a strip at the declination of the star. To increase the signal-to-noise ratio, the 13CO(2-1) and 12CO(2-1) line intensities of Figure 1 have been averaged in azimuth over 10'' wide concentric rings. The numbers in the upper left corner of each spectrum indicate the scaling ratio between the black and red line profiles (e.g. the 12CO(2-1) and 13CO(2-1) profiles). They give the \( R_{21} = \text{12CO}(2-1)/\text{13CO}(1-0) \) and \( R_{13} = \text{13CO}(2-1)/\text{12CO}(2-1) \) velocity-integrated intensity ratios directly, where the black and red line profiles have similar shapes and intensities (i.e. at radii \( r \leq 90'' \) for the left panels and \( r \geq 50'' \) for the right panels).

We have fitted with a LVG radiative transfer code included in the MADEX code (Cernicharo, 2012), the intensities of the 12CO and 13CO J=2-1 and 1-0 lines at different radii. We find that the kinetic gas temperatures \( T_k \) derived for the successive rings of Figure 1 are compatible with the temperature profile \( T_k \propto r^{-0.5} \) given by Agúndez & Cernicharo (2006), albeit \( \pm 20% \) higher. From our multi-line analysis, we find for example at \( r = 40'', 60'', \) and \( 80'' \) (corresponding to evolution times of 1700, 2600 and 3400 yr, respectively), \( n(H_2) \approx 5 \times 10^3, 2.2 \times 10^4 \) and 1.2 \( \times 10^5 \, \text{cm}^{-3} \), \( T_k \approx 20, 16 \) and 13 K. The resulting mass loss rates are all \( M_r \approx 4 \times 10^{-5} M_\odot \), with an uncertainty of a factor of \( \approx 2 \) (mainly resulting from the temperature-density near degeneracy and the uncertainty on the error beam contribution at large radii, from the difference in beam sizes at 115 GHz and 230 GHz at small radii, and from the uncertainty on the 13CO fractional abundance). For \( r = 120'' \) we find \( M_r = 3.5 \times 10^{-5} M_\odot \). These mass loss rates are within the uncertainties equal to those quoted above for \( r < 10'' \) and \( r > 180'' \).

Our study shows that the 12CO(2-1) line is very thick at small radii, and moderately thick (\( r = 4 - 2 \)) at radii larger than 40''. The 13CO lines are optically thin (\( \leq 0.1 \)), and the (2-1) 12CO and 13CO lines sub-thermally excited at radii \( r \geq 40'' \). The (2-1) line excitation becomes very low for \( r \geq 90'' \), where the average 12CO(2-1) line brightness temperature drops below 1K and the \( R_{21} = \text{13CO}(2-1)/\text{12CO}(1-0) \) ratio drops below 1. We note that the LVG models fail to reproduce the 12CO(2-1) line intensities and the \( R_{21} = \text{13CO}(2-1)/\text{12CO}(2-1) \) intensity ratio of Figure 1, both of which are a factor of 2-3 times smaller than predicted for \( 40'' \leq r \leq 80'' \). This results from an underestimation of the 12CO line opacity because of the presence of dense sub-structures in the shells. These structures appear on high-resolution interferometric CO maps (Guelin et al. in preparation), as well as on the visible-light images (Leao et al., 2006, e.g.). They are unresolved by the 11'' telescope beam and smoothed out by our azimuthal averages. They probably contain a fair fraction of the total gas mass and significantly contribute to the optically thin 12CO emission, albeit they contribute little to the optically thick 12CO(2-1) emission, which is damped. The relatively low 12CO intensities could also result from a decrease of the 12CO/13CO abundance ratio at radii \( r \geq 40'' \), however, selective photodissociation and thermal pulses, which are the mechanisms the most likely to affect this ratio, should increase, rather than decrease the 12CO/13CO ratio, making this explanation unlikely. Finally, although the J=2-1 CO lines are much less sensitive to radiative IR pumping than the J=3-2 and 1-0 lines, the effect is not negligible and may affect both \( R_{21} \) and \( R_{13} \) (see e.g. Cernicharo et al., 2014). Even though the observed values of the 12CO/13CO intensity ratio are low, they follow the predicted behaviour: high at small radii, where 12CO(2-1) is optically very thick, they are a minimum of between \( r = 30'' \) and 60'' and strongly increase at \( r > 100'' \). As for the \( R_{21} \) line intensity ratio, it is accurately reproduced by our LVG calculations.

The result of our investigation is that the mass loss rate, averaged over periods longer than the periodic modulation that gives rise to the dense shells, seems within a factor of 2 constant over the last 10^4 years. Integrated over the range \( r_i \leq r \leq r_f \), it
yields an envelope mass $M(r_{\text{loss}}) \approx 0.3 M_\odot$. The total mass lost by the star since it joined the AGB phase can be estimated to be $\approx 2 M_\odot$ from the first shell ejected 70000 yr ago (Sahai and Chronopoulos 2010).

Prior to our investigation, several attempts have been made to estimate the mass loss rate and the envelope mass. Crosas & Menten (1997) and De Beck et al. (2012) used mm and sub-mm lines of $^{13}$CO and $^{12}$CO, observed towards CW Leo or near this star, to derive a mass-loss rate averaged along the line of sight. They found values within a factor of 2 equal to ours. Other attempts were based on the dust thermal emission. Decin et al. (2011) derived from the Herschel/PACS 100 $\mu$m flux, after removing the background emission, an envelope mass of 0.23 $M_\odot$ inside a 390 $r''$ radius. For a distance of 130 pc and an expansion velocity of 14.5 km s$^{-1}$, this corresponds to an average mass loss rate $\dot{M}=1.4 \times 10^{-5} M_\odot$ yr$^{-1}$ over the last 1.7 $10^8$ yr. Those values, however, depend heavily on the assumed dust temperature profile, since the 100 $\mu$m dust emission varies as $T_d^{-3}$ (100 $\mu$m is close to the peak of the dust emission for $T_d \approx 30 K$, the average temperature in the outer envelope). They also depend on the dust emissivity coefficient and dust-to-gas mass ratio (assumed equal to 250), two parameters uncertain by factors of a few. Obviously, they depend on the accuracy of the 100 $\mu$m flux measurement, which are uncertain by a factor $\geq 2$ because of PSF artefacts (Decin et al. 2011). In view of all those uncertainties, the mass loss rate derived by Decin and coworkers is remarkably close to that we derive from CO.

Neither the high quality and high resolution CO data reported here and the FIR data from Herschel/PACS support earlier findings, based on balloon or IRAS FIR data, that the average mass-loss rate has strongly decreased in the past few thousand years (by a factor of 2 in the past 2000 yr, according to Fazio et al. 1980), and by a factor of 9 in the past 7000 yr, according to Groenewegen (1997). From an analysis of all the CO data available in 1998, using an elaborated source and radiative transfer models, Groenewegen et al. (1998) also advocated a decrease of M by a factor of 5 in the last 3000 yr. However, as pointed out by these authors, the IRAS and balloon observations lacked either angular resolution or spectral coverage, while the CO data available at that time for the outer envelope were widely discrepant. Our 30-m telescope data and the HIFI and PACS data benefit from a higher sensitivity and angular resolution. Our CO maps were observed by good weather, mostly through fast on-the-fly scanning, and are certainly much more homogeneous and more reliable than those used by Groenewegen and collaborators. We note that Teyssier et al. (2006), from a relatively recent analysis of the $^{12}$CO(1-0) through (6-5) lines, arrived at $\dot{M}=1.2 \times 10^{-5} M_\odot$ yr$^{-1}$ (1.8 $10^{-5} M_\odot$ yr$^{-1}$ scaled to our adopted distance of $D=130$ pc, and expansion velocity of 14.5 km s$^{-1}$), a value not much smaller than our value.

3.2. Interaction with the external medium and UV radiation

Actually, the IRC+10216 envelope is known to be older than 10$^7$ yr and to extend further out than shown in Figure 1. We have used the IRAM 30-m telescope for longer integration observations along a NS line extending up to 360$\circ$ N of the star. We did detect CO emission at very low level, but only at $r=240$ $r''$; we could not check, however, whether this emission corresponds to a detached shell. In the GALEX UV images, Sahai and Chronopoulos (2010) discovered a bright semi-circular rim, 12$'$ in radius centred some 4$'$ W from the star. They assign the rim to the front of the shock at the interface between the stellar wind and the surrounding gas. The 12$'$ radius already suggests

![Fig. 4. Left panel: the $^{13}$CO J=1-0 and J=2-1 line profiles (black and red histograms, respectively), averaged over concentric rings of width $\Delta r = 10''$, observed at radii ranging from $r = 0''$ to 130''. The ordinate scale (black numbers) applies to the J=1-0 line profile (black). The number in red in the upper left corner is the factor by which the J=2-1 profile (red) has been divided to match the intensity scale. For $r < 90''$ it also represents the $R_{21}=^{13}$CO(2-1)/$^{13}$CO(1-0) velocity-integrated line intensity ratio. Right panel: the J=2-1 $^{12}$CO (black) and $^{13}$CO line profiles averaged over the same 10$''$-wide rings. The ordinate scale applies to the $^{13}$CO(2-1) line profile (red). The number in black in the upper left corner is the factor by which the $^{12}$CO(2-1) profile (black) has been divided to match the intensity scale. For $r \geq 40''$, it also represents the $R_{21}=^{13}$CO(2-1)/$^{13}$CO(2-1) velocity-integrated line intensity ratio.](image-url)
an age > 3 10^4 yr. From an analysis of the rim shape, Sahai and Chronopoulos (2010) derive an age two times larger (6.9 10^4 yr).

Inside the FUV rim, the stellar wind should be freely streaming so that the shapes and motion of the expanding shells observed in the CO and dust emissions teach us about the way matter has been expelled from the stellar atmosphere. The CO distribution in the outermost shells must also be re-shaped by interstellar UV and teaches us about the ambient UV field.

Figure 1 shows that the envelope is dissymmetric and extends farther in the N-NE direction. This is particularly clear on the maps between v = 0 and -6 km s^{-1}. South-west should be the privileged direction for incoming interstellar UV radiation, as it is the direction of the Galactic Plane. The CO asymmetry may then result from photodissociation by an asymmetric UV intensity field. Alternately, it may come from the ejection mechanism, as discussed in the next section.

3.3. Mass loss mechanism

As can be seen in Figure 2, which shows the 12CO velocity-integrated emission profile at the declination of the star, the shell-intershell brightness contrast is > 3 for r > 60", the radii where the shells seem resolved by the 30-m telescope beam. Decin et al. (2011) quote a typical value of 4 for the shell-intershell contrast of the FIR dust shells. The scattered light images of the inner region also suggest a similarly large contrast (3 − 5). Mauron & Huggins (1999, 2000) Leao et al. (2006). Thus, on the scale of individual shells (the shell separation is typically 10^3 yr), the mass loss process is highly variable. Yet, as we have seen, it seems fairly stable averaged over longer timescales. Obviously, one must be looking for periodic events.

CW Leo is known to be a Mira-type variable. Mass loss is supposed to occur in Mira-type stars when the uppermost surface layers expand and become cool enough to form dust. Dust grains are accelerated outwards by the stellar radiation pressure, dragging gas on their way. However, the pulsation period of CW Leo, which is 649 days (Le Bertre, 1982), is much too short to explain the spacing between the shells. Other periodic surface expansion events are linked to thermal pulses. Those result from the periodic ignition of the helium shell that surrounds the stellar carbon core. However, their period is much too long (few×10^4 yr, Forestini & Charbonnel, 1997). The time separation between the shells, 0.5 − 1 10^3 yr, implies another mechanism.

The molecular shells of Figure 1 are not exactly centred on CW Leo. This was first noticed by Guélin et al. (1993), who pointed out that the r = 15" shell visible on the v = 0 km s^{-1} CCH and C2H maps, despite its spherical shape, was centred 2" NW of the star. The authors suggested the shift results from an orbital motion of CW Leo. The motion, caused by the presence of a companion, would impart a drift velocity to the material expelled by the star. As a consequence, a shell of gas expelled near perihelion will drift away from the star in a direction that depends on the orbital phase at the time of its ejection. The ejection phase may vary from shell to shell leading to a complex rose-window like pattern similar to that of Figure 2.

We have attempted to mimic the resulting pattern for a range of orbital parameters, using a simple model of the growth of an envelope around a binary system. Our model assumes that the mass loss rate of CW Leo is enhanced at certain phases of the orbital motion of the double star, e.g. near periastron in the case of a high eccentricity orbit. The ejection mechanism, which may be linked to the change of the Roche lobe, is not considered by itself and the ejection of matter is assumed to be spherically symmetrical with respect to CW Leo. The ejected matter is a collection of shells consisting of freely moving particles, with an expansion velocity of 14.5 km/s with respect to CW Leo. The time step in our calculations is 2 yr. Consequently, each shell has a thickness of 9.15 10^{13} cm, i.e. 1.3 stellar radii. The grav-
and the duration of the high mass loss episodes ($\dot{M}$ to 0.5 $\times 10^3$ yr). Figures 5 to 11 show different views of the matter (i.e. molecular gas) distribution in two cases of interest: constant mass loss and mass loss enhanced by a factor of 10 for a fraction of the orbit. In those examples, we assumed $M_{\text{sys}} = 3M_{\odot}$; to ease the comparison, we choose in both cases the same orbit: circular with a radius of 130 AU, and a period $P_0 = 800$ yr. The orbital velocity of CW Leo is 4.5 km s$^{-1}$.

Figure 5 shows the patterns predicted after $10^4$ yr of constant mass loss rate. The adopted gas density at $r_0$ is $3 \times 10^{10}$ cm$^{-3}$. The figure shows a pattern of over-dense ring-like structures shaped by the orbital velocity transmitted by CW Leo to each expelled shell of matter. The mass and density distributions are symmetric with respect to the orbital plane. The polar view shows a tightly wrapped spiral pattern in the orbital plane. This type of spiral structure has been observed in the envelopes of AGB stars AFGL 3068 (Mauron & Huggins 2006) and, more recently, R Sculptoris (Maercker et al., 2012). Mastrodemos & Morris (1999) (Kim and Tamm 2012), Kim et al. (2013), and He (2007) have computed several examples of such patterns. We note that the spirals appear in a natural way in binary star systems without the need of a discontinuous mass loss. The online video associated with Figure 5 shows the spatial distribution of matter as a function of time, i.e. during the growth of the envelope, from t=0 to 10000 yr. Figure 6 allows us to compare the envelope for different inclinations $i$ of the orbital plane with respect to the line of sight. The spiral structure visible for $i = 90^\circ$ gets distorted when the inclination decreases. The edge-on view of the orbital plane shows two series of circles symmetrically shifted with respect to CW Leo. To obtain a better insight and constrain the orbit inclination, we have computed the column density of gas, N($H_2$), for velocities from -14.5 km s$^{-1}$ to 14.5 km s$^{-1}$. Figure 7 shows N($H_2$) for $V-V_\odot=0$ km s$^{-1}$ and the associated online video showing the time growth of the CSE.

Figure 8 shows the pattern produced by periodic mass loss enhancements. The parameters are the same as in Figure 5. The orbital parameters are chosen to be the same as in Figures 5 through 7 to make the comparison with Figure 5 more pertinent. The mass loss integrated over one period is the same as in Figure 5, but the mass loss rate increases by a factor of 10 when the orbital phase is within 30$^\circ$ from phase 0 (i.e. periastron for an elliptical orbit). Figure 8, i.e. the periodic mass loss simulation, replicates several key features of Figure 5: i) the presence of a number of over-dense rings in the plane of the sky (see the polar view: lower right figure), some of which intersect at places, ii) increasing separation between the bright rings at large radii, and iii) asymmetrical envelope extent in the orbital plane. Figure 9 shows the total N($H_2$) at t=10000 yr for different inclinations of the orbital plane, and Figure 10 and its associated online video, N($H_2$) as a function of the gas velocity. The CO line profiles in IRC+10216, like those of most molecular lines (Cernicharo et al., 2000), show a range of velocities restricted to $V-V_\odot=-14.5$ to 14.5 km s$^{-1}$, with very sharp edges. This is consistent with a near face-on orientation of the orbital plane: A much smaller inclination of the orbital plane is integrated over all velocities. The right panel corresponds to a polar view of the CSE (line of sight perpendicular to the orbital plane) and the left panel to a view from the orbital plane. Bottom Panels: $H_2$ volume density in the plane of the sky for the same views. The figure corresponds to the last frame of an online video showing the time growth of the CSE.
Fig. 9. Total H$_2$ column density (in units of $10^{21}$ cm$^{-2}$) after 10000 yr, for the same model as Figure 8 at different inclinations of the line of view with respect to the orbital plane.

Fig. 10. Spatial distribution of matter at $t=10000$ yr for a velocity of the gas with respect to the star of 0 km s$^{-1}$ in the case of periodic mass loss (same parameters as on Figure 8). The figure corresponds to the middle frame of an online video showing the distribution of matter in the envelope at different velocities.

Figure 11 shows a comparison between the episodic mass loss model of Fig. 8 and the observations. The model data have been convolved with a Gaussian of width equal to the telescope HPBW, i.e. 11$''$. The left panels show the distribution of the gas for velocities $(V-V_*)=\pm 2$ km s$^{-1}$. The right panels show the gas column density integrated over all velocities. The upper panels correspond to the episodic mass loss model shown on Figure 8, with an orbital period of 400 yr (top panels) and 800 years (middle panels). The bottom panels show the observed $^{12}$CO (2-1) brightness distributions. Obviously, the actual gas distribution is more complex than simulated by our simple model, but the longer period of 800 years yields images much more similar to those observed. The shell-intershell density contrast appears more clearly on the narrow velocity maps (left panels).

The most likely model, according to our simulations, is that of a strongly enhanced mass-loss rate triggered every $\approx 800$ yr by the fly-by of a $\approx 1 M_\odot$ companion (the mass of cW Leo is believed to be $\approx 2 M_\odot$, Guèlin et al., 1997) on an orbit almost perpendicular to the light of sight. The orbit is probably eccentric and the high mass-loss episodes probably occur near periastron; they last long enough for CW Leo to change its orbital velocity by 1-2 rd so that the outer envelope appears asymmetric.

In this respect, it is instructive to compare both the simulated maps and the observed CO maps with the map of the dust FIR emission reported by Decin et al. (2011). This is done in Fig. 12, where we superimpose on the PSF-deconvolved and halo-subtracted PACS map (Fig. 2 of Decin et al. 2011) the intensity contour levels of our $^{12}$CO(2-1) maps (lower panels of Fig. 11). Both the integrated-velocity CO contour levels and the CO contours with $(V-V_*)=\pm 2$ km s$^{-1}$ are shown. Because dust and gas should be coeval and because the dust emission is optically thin at 100µm, dust emission should be preferably compared to the integrated-velocity CO map. Several bright FIR arc-like features appear to closely follow the bright rims of the CO shells (e.g. the rim 110$''$ N from the star, the rims 50$''$ and 100$''$SW from the star), albeit some dark FIR areas also fall atop bright CO rims (e.g. at 90$''$ W from the star). Although artefacts caused by the PACS PSF deconvolution make the comparison difficult,
would be diurnal structure induced by a companion star. The period (55 years) \( \left( V-V\prime \right) = \pm 2 \text{ km s}^{-1} \); right CO integrated over all velocities). Light blue contours levels: 1 to 6 K by steps of 1 K; yellow contours: 10 to 70 K;Kms\(^{-1}\) by 1 K;Kms\(^{-1}\). The dark blue contour levels represent 0.9 times the adjacent light blue contour levels and the green contours 0.85 times the adjacent yellow contours.

an overall correlation of the CO and FIR dust emissions seems clear.

Observations of the CO(2-1) emission, at a much higher resolution, are in progress with the SMA, the PdB Interferometer, and for the inner envelope, ALMA. The CO shells, viewed with an angular resolution of 3\(^{\prime}\) or higher appear thinner and more clumpy than in Figure [7]. These differences make it ineffectual to try to simulate the pattern of Figure [7] which is affected by beam smearing, more precisely. A definitive assessment the binary scenario must await completion of the interferometer maps.

After the submission of this article, we learned about the publication of a first ALMA study of the close surroundings \( \left( r < 3\' \right) \) of CW Leo [Decin et al., 2014], and the discovery of a faint point-like object near CW Leo that could be a companion star [Kim et al., 2014]. The \(^{13}\)CO (6-5) emission is resolved by ALMA into a central source plus a couple of arc-like features at \( \approx 2'' \) from CW Leo. Those are interpreted as part of a spiral structure induced by a companion star. The period (55 years) and orbit (diameter 20-25 AU, seen edge-on) of such a companion are however quite different from those of our model and would be difficult to reconcile with our outer envelope observations, in particular with the cusped molecular line shapes and the spherical 3D shape of the observed shells. The small field of view of the ALMA observations and lack of short spacings (which causes a negative lobes in the maps) preclude following the arc-like features at radii larger or smaller than 2", making the identification of a spiral very tentative for the time being. The arc-like features, on the other hand, could be pieces of a new shell, ejected some 80 yr ago when our model companion was near periastron.

The point-like object, discovered by Kim et al. [2014] on 2011 HST images, is interpreted by these authors as a possible companion M star. Its apparent distance from CW Leo (0.5", or 65 AU) is compatible with that of our model companion.

4. Conclusion

Our \(^{12}\)CO(2-1) and \(^{13}\)CO(2-1) line emission maps of IRC+10216, reveal the presence of over-dense spherical shells, some of which have already been noticed on optical images or in the dust thermal emission. The CO emission peaks on the central star, CW Leo, but remains relatively strong up to \( r = 180 '' \) from that star. Its intensity drops or vanishes further out. We interpret the sudden decrease of the CO brightness to photodissociation and set the photodissociation limit \( r_{\text{phot}} \) to that radius.

The CO envelope fits well inside the large bow-shock discovered by Sahai and Chronopoulos [2010] and must be freely expanding into the cavity cleared up by the shock. Outside the tiny \( (< 1'') \) dust formation region where the expelled matter is accelerated, the gas expands radially at a remarkably constant velocity: 14.5 km s\(^{-1}\). For a distance of 130 pc, the photodissociation radius corresponds to a look-back time of \( \approx 8000 \text{ yr} \). Because of CO self-shielding, CO should be a reliable tracer of the molecular gas up to \( r_{\text{phot}} \), and the \(^{12}\)CO(2-1) and \(^{13}\)CO(2-1) maps must teach us about the mass loss history in that period of time.

The over-dense shells show that the mass loss process is highly variable on timescales of hundreds of years. Previous studies suggested that the average mass loss rate has strongly decreased in the last few thousand years. Comparing the intensities of the CO lines near the star, across the envelope and beyond \( r_{\text{phot}} \) we do not see evidence of such a decrease: the mass-loss rate averaged over periods of \( 10^3 \text{ yr} \) appears to be 2-4 \( 10^{-5} M_\odot \text{ yr}^{-1} \) and to stay constant within a factor of 2, which is about the accuracy attached to our mass derivation method.

The velocity-channel \(^{12}\)CO(2-1) emission maps, particularly the map at the star velocity that traces the molecular gas in the plane of the sky, show a succession of bright circles that denote the rims of the over-dense shells. The circles are not concentric as one may expect in the case of a spherical outflow, but shifted by several arcsec in different directions; the outermost shells extend farther to the N-NE. The typical shell separation is \( 800 - 1000 \text{ yr} \) and seems to increase outwards. The shell-interstellar brightness contrast is \( \geq 3 \) in the outer envelope.

These key features can all be accounted for if CW Leo has a companion star with an eccentric orbit and if the mass loss increases when the companion is close to periastron. Another mass loss mechanism that has been proposed is a cyclic magnetic activity at the stellar surface, similar to that on the Sun (Soker [2000]). Mira-type oscillations and thermal pulses seem to be ruled out because their periods are much shorter or longer than implied by the shell separation. The angular resolution of the CO observations reported here does allow us to not properly resolve the shells and their substructures. Higher angular resolution observations are currently in progress at the SMA, PdBI, and ALMA. Hopefully, they will enable us to decide on the mass ejection mechanism and yield more reliable values of the mass-loss rate and of the shell-interstellar density contrast. The latter is of great importance for a better understanding of circumstellar chemistry (see e.g. Guélin et al. [1999] Cordiner & Millar [2009].
