ABSTRACT

Background: To evaluate the role of the traditional risk scoring system (TRSS) in detecting subclinical atherosclerosis in HIV (+) patients.

Study Design: Cohort study.

Place and Duration of Study: Infectious Diseases Clinic, Izmir Katip Çelebi University, Atatürk Training and Research Hospital, from March 2017 to January 2018.

Methodology: The patient group was formed with 52 HIV (+) patients, aged 18-60 years, and a control group was formed with 52 HIV (-) healthy volunteers. For all groups, there was no comorbid diseases or family history. Diabetes mellitus, hypertension, chronic kidney disease and cardiovascular disease were excluded from the two groups. Carotid intima-media thickness (CIMT) measurements were performed with high resolution B mode Doppler USG and patients with subclinical atherosclerosis were identified by the presence of atheroma plaque.

Results: The median right CIMT measurement was 0.91 (0.73-0.97) mm and the median left CIMT was 0.90 (0.73-0.98) mm in HIV (+) patients. The median values of CIMT on right and left sides in the control group were 0.77 (0.67-0.81) mm and 0.76 (0.70-0.81) mm. Atheroma plaque was detected in 13.5% of the HIV (+) patients and in none of the control group. Subclinical atherosclerosis was found in 51.9% of HIV (+) patients and this rate was 7.7% in the HIV (-) group (p<0.001). There was a weak correlation between CIMT and TRSS.

Conclusion: In this study, the scoring systems (Framingham, ACC/AHA CVHRS) that determine the risk of cardiovascular disease recommended in current practice and the results of CIMT measurements were not found to be compatible. The development of new scoring systems including CIMT testing for the determination of this risk will open important new horizons.

Key Words: AIDS, Cardiovascular disease, Subclinical atherosclerosis, CIMT.

INTRODUCTION

With the new-generation antiretroviral treatment (ART) options currently used in the treatment of HIV (human immunodeficiency virus), infected patients’ life expectancy is prolonged; but chronic problems that may cause, mortality may occur, if not well managed. Individuals with HIV infection are at high risk for atherosclerosis and myocardial infarction.¹ However, most of the nearly 40 million people worldwide with HIV live in developing countries and approximately 6 million of them need immediate ART.³

In the pathogenesis of atherosclerosis in HIV (+) patients, the social risks of HIV (+), the persistent inflammation caused by HIV infection and the side effects of ART used, can help explain this relationship.¹ In treatment-independent dyslipidemia in HIV (+) patients, low density lipoprotein (LDL) and high density lipoprotein (HDL) levels decrease and triglyceride (TG) and very low density lipoprotein (VLDL) levels may increase. Following treatment, TG, total cholesterol, and LDL levels may also increase.³

Exercise ECG (electrocardiogram), myocardial perfusion scintigraphy, coronary computed tomography angiography, conventional coronary angiography and carotid intima-media thickness (CIMT) measurements have been shown to be economical and non-invasive methods for the prediction of the risk of cardiovascular disease and atherosclerosis.⁴ The cardiovascular risk (CVR) of HIV (+) patients can be evaluated using the Framingham risk score (FRS-CVD-10), the Amer-
The aim of this study was to evaluate the compatibility of subclinical atherosclerosis and scoring systems for CVR through determination of CIMT.

**METHODOLOGY**

This cohort study was conducted with 52 HIV (+) patients, aged 18-60 years, who were followed up in the Infectious Diseases Clinic of İzmir Katip Çelebi University, Atatürk Training and Research Hospital and a control group was formed with 52 HIV (-) healthy volunteers. No patient or control group subject had any known diabetes mellitus, hypertension, chronic kidney disease or cardiovascular disease.

Clinical information was obtained and dietary and sports habits were questioned, then systolic / diastolic blood pressure and waist circumference were measured. Complementary laboratory tests were performed during outpatient clinic visits, including blood glucose, creatinine, blood urea nitrogen, Tc (total cholesterol), LDL, HDL, TG, AST (aspartate transaminase), ALT (alanine transaminase) and CRP (c-reactive protein). Regular exercise of ≥20 minutes ≥2 days a week was considered as an 'exercise habit'. Dietary habits were scored with respect to high carbohydrate consumption, high fatty food consumption, fast food consumption habits and salt consumption habits (very salty / less salty / no salt). A score of <8 out of a total of 9 points was accepted as 'bad dietary habit', and scores of 8 and 9 as 'good dietary habits'. Body mass index (BMI) was calculated from the height and weight values, and classified as 18.5-24.9 Kgs / m^2 = overweight, and ≥30 Kgs / m^2 = obese. HIV-related risk factors were recorded by investigating food consumption habits and salt consumption habits (very salty / less salty / no salt). A score of <8 out of a total of 9 points was accepted as 'bad dietary habit', and scores of 8 and 9 as 'good dietary habits'. Body mass index (BMI) was calculated from the height and weight values, and classified as 18.5-24.9 Kgs / m^2 = normal weight, 25-29.9 Kgs / m^2 = overweight, and ≥30 Kgs / m^2 = obese. HIV-related risk factors were recorded by investigating the CD4 count, viral load, duration of the disease, and type and duration of antiretroviral therapy. The Framingham risk score (FRS) and ACC/AHA CVDRS score were calculated.

CIMT was measured by a specialist radiologist from the Radiodiagnostic Department of the Hospital, blinded to the study groups, using a high-resolution B-mode ultrasonography (USG) device (Applio 300 Ultrasound and 11L4 linear probe, Canon). The measurements were performed manually from the right and left common carotid artery three times, and the mean thickness value was calculated. CIMT >0.9 mm or atheroma plaque was accepted as 'subclinical atherosclerosis' and high-risk for cardiovascular disease. CIMT >1.5 mm, or echogenicities extending to the lumen ≥0.5 mm or echogenicities exceeding 50% of the adjacent CIMT in the extending vessel and extending into the lumen were defined as atheroma plaque. A total of 24 (46.2%) patients were females (Table I). A regular exercise habit was determined in 41 (78.8%) HIV (+) patients and in 34 (65.4%) of the control group. A regular exercise habit was determined in 41 (78.8%) HIV (+) patients and in 34 (65.4%) of the control group.

The median body mass index of HIV (+) patients was 24.5 (22.7-29.2) kg/m^2. The median BMI of the patients in the control group was 26.2 (24.0-29.8) kg/m^2. A total of 24 (46.2%) patients (obese and overweight) in the study group and 34 (65.4%) in the control group had BMI values above normal (>24.9 kg/m^2). The mean waist circumference of 93.3 ± 12.3 cm in the HIV (+) patient group and 88.6 ± 13.0 cm in the control group. The median systolic/diastolic blood pressure values were 115.0/80.0 mmHg in the HIV (+) group, and 120.0/80.0 mmHg in the control group (Table I).

A bad dietary habit was determined in 41 (78.8%) HIV (+) patients and in 34 (65.4%) of the control group. There was no statistically significant difference in HIV (+) patients compared to the control group (p=0.126). A regular exercise habit was recorded for 38.5% (n=20) of HIV (+) patients, and 15.4% (n=8) of the control group. A regular exercise habit was seen to be statistically significantly greater in HIV (+) patients (p=0.008).

The median creatinine level was 0.82 (0.77-0.93) mg / dl in HIV (+) patients, and 0.76 (0.70-0.84) mg / dl in the control group. This increase in creatinine values in the HIV (+) patient group was statistically significant (p= 0.005). The median blood triglyceride and the mean HDLc levels were 144.5 (107.8-222.5) mg/dL and 42.1 ± 9.4 mg/dL in the HIV (+) patient group and 124.0 (89.5-167.8) mg/dL and 48.5 ± 10.5 mg/dL in the control group, respectively. There was a significant difference between TG and HDL values between the two groups (p = 0.040 and p = 0.001, respectively). In accordance with this, a statistically significant difference was observed in the calculated TG / HDL ratio (p = 0.004, Table II).
Table I: Demographic characteristics of the study and control groups.

|                      | HIV(+) patients | HIV(-) patients | p-value |
|----------------------|-----------------|-----------------|---------|
| Mean age ±SD (years) | 43.3 ±10.0      | 43 ±10.2        |         |
| Male (n,% )          | 36 (69.2%)      | 36 (69.2%)      |         |
| Median(IQR) BMI(kg/m²) | 24.5 (22.7-29.2) | 26.2 (24.0-29.8) |         |
| Overweight and obese patients (n,% ) | 24 (46.2%) | 34 (65.4%) |         |
| Mean waist circumference (cm) ±SD | 93.3±12.3 | 88.6±13.0 |         |
| Median(IQR) SBP (mmHg) | 115.0(110.0-120.0) | 120.0(110.0-120.0) |         |
| Median(IQR) DBP (mmHg) | 80.0(70.0-80.0) | 80.0(70.0-80.0) |         |

SD: Standard deviation; BMI: Body mass index; SBP: Systolic blood pressure; DBP: Diastolic blood pressure; IQR: 25th percentile-75th percentile (Interquartile range).

SD: Standard deviation; Bun: Blood urea nitrogen; Tc: Total cholesterol; LDL: Low-density lipoprotein; HDL: High-density lipoprotein; TG: Triglyceride; AST: Aspartate transaminase; ALT: Alanine transaminase; CRP: C-reactive protein; CIMT: Carotid intima media thickness; IQR: 25th percentile-75th percentile (Interquartile range).

Table III: The relationship of the groups with cardiovascular disease risk scores and biochemical parameters according to the presence of subclinical atherosclerosis.

|                      | Subclinical atherosclerosis (CIMT>0.9 mm) | Normal CIMT (CIMT≤0.9 mm) | p-value |
|----------------------|------------------------------------------|---------------------------|---------|
| FRS-CVD-10<10% (n=39)* | 46.2% (n=18)                          | 53.8% (n=21)             | 0.138   |
| ACC / AHA CVDRS <7.5%(n=22) ** | 59.1% (n=13)                          | 40.9% (n=9)              | 0.258   |
| Mean Tc±SD(mg/dL)     | 216.9±51.0                              | 185.9±37.1               | 0.016   |
| Mean LDL±SD(mg/dL)    | 138.1±42.4                              | 108.3±37.1               | 0.011   |
| Mean HDL±SD(mg/dL)    | 42.3±9.8                                | 41.9±9.1                 | 0.898   |
| Mean TG±SD(mg/dL)     | 182.9±92.3                              | 172.2±98.1               | 0.685   |
| Median (IQR) CRP mg/dL| 0.23 (0.120-0.410)                      | 0.090 (0.040-0.185)      | 0.009   |

SD: Standard deviation; Tc: Total cholesterol; LDL: Low-density lipoprotein; HDL: High-density lipoprotein; TG: Triglyceride; AST: Aspartate transaminase; ALT: Alanine transaminase; CRP: C-reactive protein; CIMT: Carotid intima media thickness; IQR: 25th percentile-75th percentile (Interquartile range); SD: Standard deviation. *Total patients for FRS-CVD-10 was 49. **Total patients for ACC / AHA CVDRS was 33, FRS-CVD-10 for patients younger than 30 years (n = 3) and ACC / AHA CVDRS for patients younger than 40 years (n = 19) could not be calculated.

The mean measurement of right CIMT in HIV (+) patients was 0.85 ± 0.16 mm and the median value was 0.91 (0.73-0.97) mm, the left CIMT was a mean of 0.88 ± 0.20 mm and a median of 0.90 (0.73-0.98) mm. In the control group, the mean value of right / left CIMT was 0.76 ± 0.12 / 0.76 ± 0.12 mm, and the median values were 0.77 (0.67-0.81) and 0.76 (0.70-0.81) mm, respectively. The CIMT values for both sides were statistically significantly increased in the HIV (+) patients (p = 0.001). Subclinical atherosclerosis (CIMT >0.9 mm) was detected in 51.9% (n=27) of HIV (+) patients, and in 4 (7.7%) in the control group. Subclinical atherosclerosis was significantly higher in HIV (+) patients than the control group (p <0.001). Atheroma plaque was detected in 13.5% (n = 7) in the HIV (+) group, and in none in the control group (Table II).

FRS-CVD-10 for patients younger than 30 years (n = 3) and ACC / AHA CVDRS for patients younger than 40 years (n = 19) could not be calculated. FRS-CVD-10 was calculated for 49 patients; 46.2% (n=18) of these patients had CIMT >0.9 and 53.8% (n=21) of these patients had CIMT ≥0.9 in FRS-CVD-10 <10% group. There was no statistical difference (p=0.138). AHA/ACC CVDRS was calculated for 33 patients; 59% (n=13) of these patients had CIMT >0.9 and 41% (n=9)
of these patients had CIMT ≥0.9 in the CVDRS <7.5% group. There was no statistical difference (p=0.258, Table III).

The median HIV (+) diagnosis time for patients was 50.0 (20.0-87.8) months. The number of patients receiving antiretroviral treatment (ART) was 51(98.1%), and the median duration of ART was 36.0 (12.0-72.0) months. Mean CD4 was 664.1 ± 342.9 cells/mm³, and mean CD8 was 829.7 ± 342.6 cells/mm³. The most common ART regimens were: protease inhibitor regimen (49%, n=25), integrase inhibitor regimen (35.3%, n=18) and non-nucleoside reverse transcriptase inhibitor regimen (15.7%, n=8).

The correlation between the presence of subclinical atherosclerosis and high-risk patients (FRS-CVD-10>10%) was evaluated by ROC analysis. There was a poor correlation between subclinical atherosclerosis and FRS-CVD-10>10% patients (AUROC:0.696; 95%CI 0.578 -0.813; p=0.002).

**DISCUSSION**

With more effective treatment of HIV infection, morbidity and mortality related to HIV has decreased and mortality rates due to chronic diseases have increased. Cardiovascular diseases (CVD) are the major reason for mortality in the chronic phase of HIV (+). The incidence of myocardial infarction in HIV (+) patients is 1.5-fold greater compared to HIV (-) individuals. In HIV (+) patients, hypertension, smoking, insulin resistance, hypercholesterolemia and smoking, which are traditional risk factors for cardiovascular disease, are more common than in the healthy population.7,8

The smoking history of the patients in the control group was 34.6%, similar to the smoking rate in Turkey;9 whereas, 69.2% of the HIV (+) patients had a history of smoking. Data on BMI in HIV-infected patients were examined and various studies have found that the prevalence of overweight or obesity ranged from 10.7% to 50%.10 In the current study, the rate of overweight or obese patients was found to be 46.2% in the HIV (+) group, and 65.4% in the control group, which was consistent with previous findings in the literature.11

Less than half of the HIV (+) patients (38.5%) had regular exercise (at least 20 minutes / day physical activity for at least two days a week). However, the rate of regular exercise was 15.4% in the control group selected from the healthy population. The fact that this ratio was higher in HIV (+) patients compared to the society average can be attributed to the fact that during outpatient clinic visits, they are encouraged and informed by physicians about the necessity for and benefits of regular physical activity.

HIV virus is known to affect the kidneys, and in addition to the virus, ART also contributes to side-effects. According to the study of Banda et al. in this study, serum creatinine levels were significantly higher in HIV (+) patients (0.82 vs. 0.76; p<0.05).12

HIV-induced immune reactions and antiretroviral therapy may exacerbate dyslipidemia. Tc, TG and LDL values may increase in patients receiving treatment and HDL may decrease.13 In the current study, TG levels were significantly increased in HIV (+) patients (144.5 vs. 124.0 mg/dL, p=0.040) and HDL levels were significantly decreased (42.1 ± 9.4 and 48.5 ± 10.5mg/dL; p = 0.001). TC (202.0 ± 47.1-197.6 ± 39.5) and LDL (132.8 ± 42.3-124.1±36.2) values were similar in both groups. Similar LDL and TC levels can be explained by the fact that the duration of treatment of the HIV (+) patient group was shorter than in other studies (median 36 months).

The use of CIMT measurement is recommended in asymptomatic patients to determine increased risk of cardiovascular disease.14 In the current study, CIMT measurements were taken in both groups to investigate whether HIV (+) patients are at increased cardiovascular risk, for which medical and social measures can be taken. The median values of both right and left CIMT were significantly increased in the HIV (+) patient group compared to the HIV negative group (right: 0.91 vs 0.77 and left: 0.90 vs 0.76, both p = 0.001). The presence of atheroma plaque was detected in 13.5% (n=7) of HIV (+) patients, and not detected in any of the HIV (-) group. When similar studies in the literature were examined, CIMT measurements were found to be significantly increased in HIV (+) patients.15

In a study by Mosepele et al., HIV (+) patients were compared with an HIV (-) control group and no significant difference was found between the groups with respect to the CIMT measurements, but atheroma plaque was determined at a significantly higher rate in the HIV (+) group.16 Hsue et al. also reported that even after adjusting for traditional risk factors, a higher CIMT measurement value was found in HIV (+) patients.17 In the current study, although the mean age was the same in both groups, a significant difference was found in terms of CIMT measurements (p = 0.001, Table II).

Patients with CIMT >0.9 mm and/or atheroma plaque have been categorised as 'subclinical atherosclerosis'. De Socio et al. detected subclinical atherosclerosis at a rate of 41% at HIV (+) patients.18 In the current study, subclinical atherosclerosis was determined in 51.9% (n=27) of the HIV (+) patient group and in 7.7% (n=2) of the control group. The rate of subclinical atherosclerosis of 51.9% was higher than in other studies in the literature.

According to this study, in a subgroup evaluation of 279 HIV (+) patients in Brazil, atherosclerosis was found to be associated with age and BMI, but gender and smoking habit were unrelated.19

Current guidelines for cardiovascular risk management in HIV (+) patients recommend to determine the possible risk using the FRS-CVD-10 and ACC / AHA CVDRS.13 However, these scores may be insufficient to determine the actual risk
in the HIV population.\textsuperscript{20,21} In a study evaluating 84 HIV (+) patients with a low Framingham risk score (median FRS: 1%), the prevalence of subclinical carotid atherosclerosis was found to be high (21%) and it was stated that these patients, evaluated according to FRS, were overlooked and did not receive primary prophylaxis for cardiovascular events.\textsuperscript{22} In the current study, there were 26 HIV (+) patients with FRS-CVD-10 calculated, who had subclinical atherosclerosis, and only 30.8% (n=8) patients in the subclinical atherosclerosis group were at moderate and high risk (≥10%), while 69.2% (n=18) were at low risk (<10%), according to the the FRS-CVD-10. There were 39 patients with a total FRS-CVD-10 <10% in the HIV (+) group, with subclinical atherosclerosis present in 46.2% of these patients with a low risk according to the FRS-CVD-10 (Table III). Correlation analysis showed a weak correlation between the CIMT measured values and the calculated FRS-CVD-10 scores, with a sensitivity of 30% for the presence of subclinical atherosclerosis. According to this, it was seen as a possible problem that patients who were found to be at low risk with FRS-CVD-10 could be overlooked and the necessary precautions and treatments would not be implemented.

The cardiovascular disease risk score (DAD CVDRS) is a scoring system that takes into account the risks associated with the use of ART in the HIV (+) patient population. Thompson-Paul et al. compared the SCORE and DAD CVD risk scores known as ASCV and FRS, and European scores in the HIV (+) population, and found that the FRS and DAD CVD risk scores were calculated and no superiority was found for either scoring system. The positive predictive value of both scoring systems was moderate.\textsuperscript{23}

In the current study, the mean values of Tc (216.9 ± 51-185.9 ± 37.1) mm and LDL (138.1 ± 42.4-108.3 ± 37.1) mm were significantly increased in the group with subclinical atherosclerosis (p= 0.016-0.011). TG levels showed a mild increase (182.9 ± 92.3 vs.172.2 ± 98.1) mm, while HDL levels were similar (Table III). This result may also be related to the fact that patients exposed to ART for a longer time (>24 months) were more likely to be in the subclinical atherosclerosis group. Increased CRP levels have been associated with a slower immunological response and increased risk of cardiovascular disease.\textsuperscript{24} In the current study, CRP levels were found to be significantly increased in the subclinical atherosclerosis group (p = 0.009, Table III).

**CONCLUSION**

Subclinical atherosclerosis may be present in patients with low risk scores according to FRS-CVD-10 and ACC / AHA CVDRS. Considering the CIMT cut-off value as 0.9, the use of CIMT for the same purpose in HIV (+) patients is recommended for ease of use, low cost and reproducibility. Therefore, the creation of a more powerful scoring system including CIMT measurements could lead to more effective results in determining cardiovascular risk in HIV (+) patients.
