Abstract. Strategy improvement is a widely-used and well-studied class of algorithms for solving graph-based infinite games. These algorithms are parameterized by a switching rule, and one of the most natural rules is “all switches” which switches as many edges as possible in each iteration. Continuing a recent line of work, we study all-switches strategy improvement from the perspective of computational complexity. We consider two natural decision problems, both of which have as input a game $G$, a starting strategy $s$, and an edge $e$. The problems are: 1.) The edge switch problem, namely, is the edge $e$ ever switched by all-switches strategy improvement when it is started from $s$ on game $G$? 2.) The optimal strategy problem, namely, is the edge $e$ used in the final strategy that is found by strategy improvement when it is started from $s$ on game $G$? We show PSPACE-completeness of the edge switch problem and optimal strategy problem for the following settings: Parity games with the discrete strategy improvement algorithm of Vöge and Jurdziński; mean-payoff games with the gain-bias algorithm [14,37]; and discounted-payoff games and simple stochastic games with their standard strategy improvement algorithms. We also show PSPACE-completeness of an analogous problem to edge switch for the bottom-antipodal algorithm for finding the sink of an Acyclic Unique Sink Orientation on a cube.

1. Introduction

In this paper we study strategy improvement algorithms for solving two-player games such as parity games, mean-payoff games, discounted games, and simple stochastic games [24,37,43]. These games are interesting both because of their important applications and their unusual complexity status. Parity games, for example, arise in several areas of theoretical computer science, for example, in relation to the emptiness problem for tree automata [6,22] and as an algorithmic formulation of model checking for the modal $\mu$-calculus [7,41]. Moreover, all of these problems are in $\text{NP} \cap \text{coNP}$, and even $\text{UP} \cap \text{coUP}$ [3,26], so they are unlikely to be $\text{NP}$-complete. However, despite much effort from the community, none of these problems are known to be in $\text{P}$, and whether there exists a polynomial-time algorithm to solve these games is a very important and long-standing open problem.

Strategy improvement is a well-studied method for solving these games [24,37,43]. It is an extension of the well-known policy iteration algorithms for solving Markov decision
processes. The algorithm selects one of the two players to be the strategy improver. Each strategy of the improver has a set of switchable edges, and switching any subset of these edges produces a strictly better strategy. So, the algorithm proceeds by first choosing an arbitrary starting strategy, and then in each iteration, switching some subset of the switchable edges. Eventually this process will find a strategy with no switchable edges, and it can be shown that this strategy is an optimal strategy for the improver.

To completely specify the algorithm, a switching rule is needed to pick the subset of switchable edges in each iteration (this is analogous to the pivot rule used in the simplex method). Many switching rules have been proposed and studied [9, 23, 30, 31, 38]. One of the most natural rules, and the one that we consider in this paper, is the all-switches rule, which always switches a vertex if it has a switchable edge. In particular, we consider greedy all-switches, which chooses the best edge whenever more than one edge is switchable at a vertex (ties are broken arbitrarily). For a long time, the all-switches variant of the discrete strategy improvement algorithm of Vöge and Jurdziński [43] was considered the best candidate for a polynomial-time algorithm to solve parity games. Indeed, no example was known that required a super-linear number of iterations. However, these hopes were dashed when Friedmann showed an exponential lower bound for greedy all-switches strategy improvement for parity games [15]. In the same paper, he showed that his result extends to strategy improvement algorithms for discounted games and simple stochastic games.

The computational power of pivot algorithms. In this paper, we follow a recent line of work that seeks to explain the poor theoretical performance of pivoting algorithms using a complexity-theoretic point of view. The first results in this direction were proved for problems in the complexity classes PPAD and PLS. It is known that, if a problem is tight-PLS-complete then computing the solution found by the natural improvement algorithm is PSPACE-complete [25]. Similarly, for the canonical PPAD-complete problem End-of-the-Line, computing the solution that is found by the natural line following algorithm is PSPACE-complete [35]. This was extended to show that is PSPACE-complete to compute any of the solutions that can be found by the Lemke-Howson algorithm [21], a pivoting algorithm that solves the PPAD-complete problem of finding a Nash equilibrium of a bimatrix game.

Until recently, results of this type were only known for algorithms for problems that, due to known hardness results, are unlikely to lie in P. However, a recent series of papers has shown that similar results hold even for the simplex method for linear programming. Adler, Papadimitriou and Rubinstein [1] showed that there exists an artificially contrived pivot rule for which is PSPACE-complete to decide if a given basis is on the path of bases visited by the simplex algorithm with this pivot rule. Disser and Skutella [5] studied the natural pivot rule that Dantzig proposed when he introduced the simplex method, and they showed that it is NP-hard to decide whether a given variable enters the basis when the simplex method is run with this pivot rule. Finally, Fearnley and Savani strengthened both these results by showing that the decision problem that Disser and Skutella considered is actually PSPACE-complete [12], and they also showed that determining if a given variable is used in the final optimal solution found by the algorithm is PSPACE-complete. This result exploited a known connection between single-switch policy iteration for Markov Decision Processes (MDPs) and the simplex method for a corresponding linear program (LP). The result was first proved for a greedy variant of single-switch policy iteration, which then implied the result for the simplex method with Dantzig’s pivot rule.
All of the results on linear programming are motivated by the quest to find a strongly polynomial algorithm for linear programming, which was included in Smale’s list of great unsolved problems of the 21st century [40]. One way of resolving this problem would be to design a polynomial-time pivot rule for the simplex method, and if we are to do this, then it is crucial to understand why existing pivot rules fail. The PSPACE-completeness indicates that they fail because in fact they can do something far more than is necessary, namely they are capable of solving any problem that can be computed in polynomial space.

We face a similar quest to find a polynomial-time algorithm for the games studied in this paper. Strategy improvement is a prominent algorithm for solving these games, and indeed it is one of the only algorithms for solving discounted and simple stochastic games. So, devising a polynomial-time switching rule is an obvious direction for further study. It may in fact be easier to devise a polynomial time switching rule, because there is a lot more freedom in each step of the algorithm: simplex pivot rules correspond to switching rules that can only switch a single edge, whereas strategy improvement rules can switch any subset of edges. Indeed, it may be the case that the polynomial Hirsch conjecture fails, ruling out a strongly polynomial simplex method, even though the analogue of the Hirsch conjecture for strategy improvement is known to be true: one can always reach an optimal strategy in at most $n$ strategy improvement iterations, where $n$ is the number of vertices in the game.

Our contribution. Our main results are that, for greedy all-switches strategy improvement, determining whether the algorithm switches a given edge is PSPACE-complete, and determining whether the optimal strategy found by the algorithm uses a particular edge is PSPACE-complete. One of the key features that strategy improvement has is the ability to switch multiple switchable edges at the same time, rather than just one as in the simplex method. Our results show that naively using this power does not help to avoid the PSPACE-completeness results that now seem to be endemic among pivoting algorithms. The proof primarily focuses on the strategy improvement algorithm of Vögge and Jurdziński for solving parity games [43]. The following definition formalises the problem that we are interested in.

Definition 1.1. Let $G$ be a game, and let $e$ be an edge and $\sigma$ be a strategy profile of $G$. The problem $\text{EdgeSwitch}(G,\sigma,e)$ is to decide if the edge $e$ is ever switched by greedy all-switches strategy improvement when it is applied to $G$ starting from $\sigma$.

The main technical contribution of the paper is to show the following theorem.

Theorem 1.2. $\text{EdgeSwitch}$ for Vögge and Jurdziński’s algorithm is PSPACE-complete.

We use this theorem to show similar results for other games. For mean-payoff games, our results apply to the gain-bias algorithm [14]; and for discounted and simple stochastic games our results apply to the standard strategy improvement algorithms [4, 36]. We utilise the well-known polynomial-time reductions from parity games to mean-payoff games to mean-payoff games [36], mean-payoff games to discounted games, and from discounted games to simple stochastic games [44]. The parity games we construct have the property that when they are reduced to the other games mentioned above strategy improvement will behave in the same way (for discounted and simple stochastic games this was already observed by Friedmann [15]), so we get the following corollary of Theorem 1.2.

Corollary 1.3. $\text{EdgeSwitch}$ for the gain-bias algorithm, and the standard strategy improvement algorithms for discounted-payoff and simple stochastic games is PSPACE-complete.
Theorem 1.2 proves a property about the path taken by strategy improvement during its computation. Previous results have also studied the complexity of finding the optimal strategy that is produced by strategy improvement, which we encode in the following problem.

**Definition 1.4.** Let $G$ be a game, and let $e$ be an edge and $\sigma$ be a strategy profile of $G$. The problem $\text{OptimalStrategy}(G, \sigma, e)$ is to decide if the edge $e$ is used in the optimal strategy that is found by greedy all-switches strategy improvement when applied to $G$ starting from $\sigma$.

Augmenting our construction for parity games with an extra gadget gives the following theorem.

**Theorem 1.5.** $\text{OptimalStrategy}$ for Vöge and Jurdziński’s algorithm is PSPACE-complete.

This result requires that the parity games that we construct have multiple optimal solutions because otherwise the PSPACE hardness of $\text{OptimalStrategy}$ would imply $\text{NP} \cap \text{coNP} = \text{PSPACE}$. With further modifications, we can again extend this result to strategy improvement algorithms for other games.

**Corollary 1.6.** $\text{OptimalStrategy}$ for the gain-bias algorithm, and the standard strategy improvement algorithms for discounted-payoff and simple stochastic games is PSPACE-complete.

Our results can also be applied to unique sink orientations (USOs). An orientation of an $n$-dimensional hypercube is a function that assigns a direction to each edge of the cube. The faces of an $n$-dimensional cube are the $k$-dimensional cubes that can be obtained by fixing $n-k$ of the dimensions and letting the other dimensions be free. An orientation is a USO if every face of the cube has a unique sink [42].

Recently, it was shown that recognising a USO is coNP-complete, and that recognising an acyclic USO (AUSO) is PSPACE-complete [20]. As we will see, the games that we consider will be guaranteed to induce AUSOs. The fundamental algorithmic problem for USOs is to find the global sink assuming oracle access to the edge orientation. The design and analysis of algorithms for this problem is an active research area [16,17,19,23,33,39], in particular for AUSOs. The BottomAntipodal algorithm [39] for AUSOs on cubes starts at an arbitrary vertex and in each iteration jumps to the antipodal vertex in the sub-cube spanned by the outgoing edges at the current vertex.

For binary games, where vertices have outdegree at most two, the valuation functions used by strategy improvement induce an AUSO on a cube, and all-switches strategy improvement corresponds to BottomAntipodal on this AUSO. For non-binary games we instead get an AUSO on a grid [18], so our results immediately give a PSPACE-hardness result for grid USOs for a problem analogous to EdgeSwitch. To get a similar result for AUSOs on cubes we turn our construction into a binary parity game, and we get the following.

**Corollary 1.7.** Let $C$ be a $d$-dimensional cube AUSO, specified by a poly($d$)-sized circuit that computes the edge orientations for each vertex of $C$. Given a dimension $k \in \{1, \ldots, d\}$, and a vertex $v$, it is PSPACE-complete to decide if BottomAntipodal started at $v$, ever switches the $k$th coordinate.

Since a USO has a unique solution, by definition, we cannot hope to get a result for AUSOs that is analogous to OptimalStrategy, since, as noted above, PSPACE-hardness of
OptimalStrategy requires multiple optimal solutions under standard complexity-theoretic assumptions.

**Related work.** The best known algorithms for mean-payoff, discounted, and simple stochastic games have subexponential running time: the random facet strategy improvement algorithms combine strategy improvement with the random-facet algorithm for LPs [30–32]. Following the work of Friedmann [15] that we build on heavily in this paper, Friedmann, Hansen, and Zwick showed a sub-exponential lower bound for the random facet strategy improvement algorithm [16]. They also used a construction of Fearnley [8] to extend the bound to the random facet pivot rule for the simplex method [17].

For parity games, there are several algorithms that perform better than random facet strategy improvement. First, a deterministic subexponential-time algorithm was found [28]. Very recent work has improved this even further by producing an algorithm that uses quasi-polynomial time and space [2], and it has subsequently been shown that there are algorithms that use quasi-polynomial time and polynomial space [10,27].

**Roadmap.** In Section 2, we give a formal definition of parity games, and more specifically the one-sink games used by Friedmann that we also use for our construction. We then give a high-level overview of how all-switches strategy improvement works. Our main reduction starts with an iterated circuit evaluation problem. In Section 3, we describe our main construction of a parity game that will implement iterated circuit iteration when strategy improvement is run on it. In Section 4, we describe the sequence of strategies that all-switches strategy improvement will go through as it implements the iterated circuit evaluation. In Section 5, we show that the construction works as claimed and thus prove that EdgeSwitch is PSPACE-hard for parity games. In Section 6, we show how this result for EdgeSwitch extends to strategy improvement algorithms for other games. In Section 7, we show how to augment our construction with an extra gadget to give PSPACE-hardness results for OptimalStrategy. In Section 8, we state some open problems.

2. Preliminaries

2.1. Parity games. A parity game is defined by a tuple \( G = (V, V_{\text{Even}}, V_{\text{Odd}}, E, \text{pri}) \), where \((V, E)\) is a directed graph. The sets \( V_{\text{Even}} \) and \( V_{\text{Odd}} \) partition \( V \) into the vertices belonging to player Even, and the vertices belonging to player Odd, respectively. The priority function \( \text{pri} : V \to \{1, 2, \ldots\} \) assigns a positive natural number to each vertex. We make the standard assumption that there are no terminal vertices, which means that every vertex is required to have at least one outgoing edge. The strategy improvement algorithm of Vöge and Jurdziński also requires that we assume, without loss of generality, that every priority is assigned to at most one vertex.

A strategy for player Even is a function that picks one outgoing edge for each Even vertex. More formally, a deterministic positional strategy for Even is a function \( \sigma : V_{\text{Even}} \to V \) such that, for each \( v \in V_{\text{Even}} \) we have that \((v, \sigma(v)) \in E\). Deterministic positional strategies for player Odd are defined analogously. Throughout this paper, we will only consider deterministic positional strategies, and from this point onwards, we will refer to them simply as strategies. We use \( \Sigma_{\text{Even}} \) and \( \Sigma_{\text{Odd}} \) to denote the set of strategies for players Even and Odd, respectively.
A play of the game is an infinite path through the game. More precisely, a play is a sequence $v_0, v_1, \ldots$ such that for all $i \in \mathbb{N}$ we have $v_i \in V$ and $(v_i, v_{i+1}) \in E$. Given a pair of strategies $\sigma \in \Sigma_{\text{Even}}$ and $\tau \in \Sigma_{\text{Odd}}$, and a starting vertex $v_0$, there is a unique play that occurs when the game starts at $v_0$ and both players follow their respective strategies. So, we define $\text{Play}(v_0, \sigma, \tau) = v_0, v_1, \ldots$, where for each $i \in \mathbb{N}$ we have $v_{i+1} = \sigma(v_i)$ if $v_i \in V_{\text{Even}}$, and $v_{i+1} = \tau(v_i)$ if $v_i \in V_{\text{Odd}}$.

Given a play $\pi = v_0, v_1, \ldots$ we define $\text{MaxIo}(\pi) = \max \{ p : \exists$ infinitely many $i \in \mathbb{N}$ s.t. $\text{pri}(v_i) = p \}$, to be the maximum priority that occurs infinitely often along $\pi$. We say that a play $\pi$ is winning for player Even if $\text{MaxIo}(\pi)$ is even, and we say that $\pi$ is winning for Odd if $\text{MaxIo}(\pi)$ is odd. A strategy $\sigma \in \Sigma_{\text{Even}}$ is a winning strategy for a vertex $v \in V$ if, for every strategy $\tau \in \Sigma_{\text{Odd}}$, we have that $\text{Play}(v, \sigma, \tau)$ is winning for player Even. Likewise, a strategy $\tau \in \Sigma_{\text{Odd}}$ is a winning strategy for $v$ if, for every strategy $\sigma \in \Sigma_{\text{Even}}$, we have that $\text{Play}(v, \sigma, \tau)$ is winning for player Odd. The following fundamental theorem states that parity games are positionally determined.

**Theorem 2.1** ([6,34]). In every parity game, the set of vertices $V$ can be partitioned into winning sets $(W_0, W_1)$, where Even has a positional winning strategy for all $v \in W_0$, and Odd has a positional winning strategy for all $v \in W_1$.

The computational problem that we are interested in is, given a parity game, to determine the partition $(W_0, W_1)$.

### 2.2. Strategy improvement

We now describe the strategy improvement algorithm of Vöge and Jurdziński [43] for solving parity games, which will be the primary focus of this paper.

**Valuations.** The algorithm assigns a valuation to each vertex $v$ under every pair of strategies $\sigma \in \Sigma_{\text{Even}}$ and $\tau \in \Sigma_{\text{Odd}}$. Since both of these strategies are positional, we know that $\text{Play}(v, \sigma, \tau)$ consists of a finite initial path followed by an infinitely repeated simple cycle. Let $p$ be the largest priority that is seen infinitely often along $\text{Play}(v, \sigma, \tau)$. Since every priority is assigned to at most one vertex, there is a unique vertex $u$ with $\text{pri}(u) = p$. We use this vertex to decompose the play: let $P(v, \sigma, \tau)$ be the finite simple path that starts at $v$ and ends at $u$, and let $C(v, \sigma, \tau)$ be the infinitely-repeated cycle that starts at $u$ and ends at $u$. We can now define the valuation function $\text{Val}^{\sigma,\tau}_{VJ}(v) = (p, S, d)$ where $p$ is as above and:

- $S$ is the set of priorities on the finite path that are strictly greater than $p$:
  \[ S = \{ \text{pri}(u) : u \in P(v, \sigma, \tau) \text{ and } \text{pri}(u) > p \} \].
- $d$ is the length of the finite path: $d = |P(v, \sigma, \tau)|$.

We now define an order over valuations. First we define an order $\preceq$ over priorities: we have that $p \prec q$ if one of the following holds:
- $p$ is odd and $q$ is even.
- $p$ and $q$ are both even and $p < q$.
- $p$ and $q$ are both odd and $p > q$. 

Furthermore, we have that $p \leq q$ if either $p < q$ or $p = q$.

Next we define an order of the sets of priorities that are used in the second component of the valuation. Let $P, Q \subset \mathbb{N}$. We first define:

$$\text{MaxDiff}(P, Q) = \max\((P \setminus Q) \cup (Q \setminus P))\).$$

If $d = \text{MaxDiff}(P, Q)$ then we define $P \sqsubset Q$ to hold if one of the following conditions holds:

- $d$ is even and $d \in Q$.
- $d$ is odd and $d \in P$.

Furthermore, we have that $P \sqsubseteq Q$ if either $P = Q$ or $P \sqsubset Q$.

Finally, we can provide an order over valuations. We have that $(p, S, d) \prec (p', S', d')$ if one of the following conditions holds:

- $p < p'$.
- $p = p'$ and $S \sqsubset S'$.
- $p = p'$ and $S = S'$ and $p$ is odd and $d < d'$.
- $p = p'$ and $S = S'$ and $p$ is even and $d > d'$.

Furthermore, we have that $(p, S, d) \preceq (p', S', d')$ if either $(p, S, d) \prec (p', S', d')$ or $(p, S, d) = (p', S', d')$.

**Best responses.** Given a strategy $\sigma \in \Sigma_{\text{Even}}$, a best response against $\sigma$ is a strategy $\tau^* \in \Sigma_{\text{Odd}}$ such that, for every $\tau \in \Sigma_{\text{Odd}}$ and every vertex $v$ we have $\text{Val}_{VJ}^{\tau}(v) \leq \text{Val}_{VJ}^{\tau^*}(v)$. Vöge and Jurdziński proved the following properties.

**Lemma 2.2** ([43]). For every $\sigma \in \Sigma_{\text{Even}}$, a best response $\tau^*$ can be computed in polynomial time.

We define $\text{Br}(\sigma)$ to be an arbitrarily chosen best response strategy against $\sigma$. Furthermore, we define $\text{Val}_{VJ}^{\sigma}(v) = \text{Val}_{VJ}^{\sigma,\text{Br}(\sigma)}(v)$.

**Switchable edges.** Let $\sigma$ be a strategy and $(v, u) \in E$ be an edge such that $\sigma(v) \neq u$. We say that $(v, u)$ is switchable in $\sigma$ if $\text{Val}_{VJ}^{\sigma}(\sigma(v)) \prec \text{Val}_{VJ}^{\sigma}(u)$. Furthermore, we define a most appealing outgoing edge at a vertex $v$ to be an edge $(v, u)$ such that, for all edges $(v, u')$ we have $\text{Val}_{VJ}^{\sigma}(u') \preceq \text{Val}_{VJ}^{\sigma}(u)$.

There are two fundamental properties of switchable edges that underlie the strategy improvement technique. The first property is that switching any subset of the switchable edges will produce an improved strategy. Let $\sigma$ be a strategy, and let $W \subseteq E$ be a set of switchable edges in $\sigma$ such that, for each vertex $v$, there is at most one edge of the form $(v, u) \in W$. Switching $W$ in $\sigma$ creates a new strategy $\sigma[W]$ where for all $v$ we have:

$$\sigma[W](v) = \begin{cases} u & \text{if } (v, u) \in W, \\ \sigma(v) & \text{otherwise.} \end{cases}$$

We can now formally state the first property.

**Lemma 2.3** ([43]). Let $\sigma$ be a strategy and let $W \subseteq E$ be a set of switchable edges in $\sigma$ such that, for each vertex $v$, there is at most one edge of the form $(v, u) \in W$. We have:

- For every vertex $v$ we have $\text{Val}_{VJ}^{\sigma}(v) \preceq \text{Val}_{VJ}^{\sigma[W]}(v)$.
- There exists a vertex $v$ for which $\text{Val}_{VJ}^{\sigma}(v) \prec \text{Val}_{VJ}^{\sigma[W]}(v)$. 
The second property concerns strategies with no switchable edges. A strategy $\sigma \in \Sigma_{\text{Even}}$ is optimal if for every vertex $v$ and every strategy $\sigma' \in \Sigma_{\text{Even}}$ we have $\text{Val}_{VJ}^\sigma(v) \preceq \text{Val}_{VJ}^{\sigma'}(v)$.

**Lemma 2.4** ([43]). A strategy with no switchable edges is optimal.

Vöge and Jurdiński also showed that winning sets for both players can be extracted from an optimal strategy. If $\sigma$ is an optimal strategy, then $W_0$ contains every vertex $v$ for which the first component of $\text{Val}_{VJ}^\sigma(v)$ is even, and $W_1$ contains every vertex $v$ for which the first component of $\text{Val}_{VJ}^\sigma(v)$ is odd. Hence, to solve the parity game problem, it is sufficient to find an optimal strategy.

**The algorithm.** The two properties that we have just described give rise to an obvious strategy improvement algorithm that finds an optimal strategy. The algorithm begins by selecting an arbitrary strategy $\sigma \in \Sigma_{\text{Even}}$. In each iteration, the algorithm performs the following steps:

1. If there are no switchable edges, then terminate.
2. Otherwise, select a set $W \subseteq E$ of switchable edges in $\sigma$ such that, for each vertex $v$, there is at most one edge of the form $(v, u) \in W$.
3. Set $\sigma := \sigma[W]$ and go to step 1.

By the first property, each iteration of this algorithm produces a strictly better strategy according to the $\prec$ ordering, and therefore the algorithm must eventually terminate. However, the algorithm can only terminate when there are no switchable edges, and therefore the second property implies that the algorithm will always find an optimal strategy.

The algorithm given above does not specify a complete algorithm, because it does not specify which subset of switchable edges should be chosen in each iteration. Indeed, there are many variants of the algorithm that use a variety of different switching rules. In this paper, we focus on the greedy all-switches switching rule. This rule switches every vertex that has a switchable edge, and if there is more than one switchable edge, it arbitrarily picks one of the most appealing edges.

**One-sink games.** Friedmann observed that, for the purposes of showing lower bounds, it is possible to simplify the Vöge-Jurdiński algorithm by restricting the input to be a one-sink game [15].

A one-sink parity game contains a sink vertex $s$ such that $\text{pri}(s) = 1$. An even strategy $\sigma \in \Sigma_{\text{Even}}$ is called a terminating strategy if, for every vertex $v$, the first component of $\text{Val}_{VJ}^\sigma(v)$ is 1. This means that, when the opponent plays optimally against $\sigma$, the play will terminate in the sink $s$. Formally, a parity game is a one-sink parity game if:

- There is a vertex $s \in V$ such that $\text{pri}(s) = 1$, and $(s, s)$ is the only outgoing edge from $s$. Furthermore, there is no vertex $v$ with $\text{pri}(v) = 0$.
- All optimal strategies are terminating.

Now, suppose that we apply the Vöge-Jurdiński algorithm, and furthermore suppose that the initial strategy is terminating. Since the initial and optimal strategies are both terminating, we have that, for every strategy $\sigma$ visited by the algorithm and every vertex $v$, the first component of $\text{Val}_{VJ}^\sigma(v) = 1$, and so it can be ignored. Furthermore, since there is no vertex with priority 0, the second component of $\text{Val}_{VJ}^\sigma(v)$ must be different from the second component of $\text{Val}_{VJ}^\sigma(u)$, for every $v, u \in V$. Therefore, the third component of the valuation can be ignored.
Thus, for a one-sink game, we can define a simplified version of the Vöge-Jurdziński algorithm that only uses the second component. So, we define \( \text{Val}^2(v) \) to be equal to the second component of \( \text{Val}^2_{\text{J}}(v) \), and we carry out strategy improvement using the definitions given above, but with \( \text{Val}^2(v) \) substituted for \( \text{Val}^2_{\text{J}}(v) \). Note, in particular, that in this strategy improvement algorithm, and edge \((v,u)\) is switchable in \( \sigma \) if \( \text{Val}^2(\sigma(v)) \supseteq \text{Val}^2(\sigma(u)) \).

In our proofs, we will frequently want to determine the maximum difference between two valuations. For this reason, we introduce the following notation. For every strategy \( \sigma \), and every pair of vertices \( v, u \in V \), we define \( \text{MaxDiff}^\sigma(v,u) = \text{MaxDiff}(\text{Val}^\sigma(v), \text{Val}^\sigma(u)) \).

### 2.3. Circuit iteration problems.

To prove our \( \text{PSPACE} \)-completeness results, we will reduce from two circuit iteration problems, which we now define.

**The problems.** A circuit iteration instance is a triple \((F,B,z)\), where:

- \( F : \{0,1\}^n \to \{0,1\}^n \) is a function represented as a boolean circuit \( C \),
- \( B \in \{0,1\}^n \) is an initial bit-string, and
- \( z \) is an integer such that \( 1 \leq z \leq n \).

We use standard notation for function iteration: given a bit-string \( B \in \{0,1\}^n \), we recursively define \( F^1(B) = F(B) \), and \( F^i(B) = F(F^{i-1}(B)) \) for all \( i > 1 \).

We now define two problems that will be used as the starting point for our reduction. Both are decision problems that take as input a circuit iteration instance \((F,B,z)\).

- **BitSwitch** \((F,B,z)\): decide whether there exists an even \( i \leq 2^n \) such that the \( z \)-th bit of \( F^i(B) \) is 1.
- **CircuitValue** \((F,B,z)\): decide whether the \( z \)-th bit of \( F^{2^n}(B) \) is 1.

The requirement for \( i \) to be even in \( \text{BitSwitch} \) is a technical requirement that is necessary in order to make our reduction to strategy improvement work.

The fact that these problems are \( \text{PSPACE} \)-complete should not be too surprising, because \( F \) can simulate a single step of a space-bounded Turing machine, so when \( F \) is iterated, it simulates a run of the space-bounded Turing machine. The following result was shown in [12].

**Lemma 2.5.** [12, Lemma 7] **BitSwitch** and **CircuitValue** are \( \text{PSPACE} \)-complete.

**Circuits.** For the purposes of our reduction, we must make some assumptions about the format of the circuits that represent \( F \). Let \( C \) be a boolean circuit with \( n \) input bits, \( n \) output bits, and \( k \) gates. We assume, w.l.o.g., that all gates are or-gates or not-gates. The circuit will be represented as a list of gates indexed 1 through \( n + k \). The indices 1 through \( n \) represent the \( n \) inputs to the circuit. Then, for each \( i > n \), we have:

- If gate \( i \) is an or-gate, then we define \( I_1(i) \) and \( I_2(i) \) to give the indices of its two inputs.
- If gate \( i \) is a not-gate, then we define \( I(i) \) to give the index of its input.

The gates \( k + 1 \) through \( k + n \) correspond to the \( n \) output bits of the circuit, respectively. For the sake of convenience, for each input bit \( i \), we define \( I(i) = k + i \), which indicates that, if the circuit is applied to its own output, input bit \( i \) should copy from output bit \( I(i) \). Moreover, we assume that the gate ordering is topological. That is, for each or-gate \( i \) we assume that \( i > I_1(i) \) and \( i > I_2(i) \), and we assume that for each not-gate \( i \) we have \( i > I(i) \).

For each gate \( i \), let \( d(i) \) denote the depth of gate \( i \), which is the length of the longest path from \( i \) to an input bit. So, in particular, the input bits are at depth 0. Observe that we can increase the depth of a gate by inserting dummy or-gates: given a gate \( i \), we can add
an or-gate \( j \) with \( I_1(j) = i \) and \( I_2(j) = i \), so that \( d(j) = d(i) + 1 \). We use this fact in order to make the following assumptions about our circuits:

- For each or-gate \( i \), we have \( d(I_1(i)) = d(I_2(i)) \).
- There is a constant \( c \) such that, for every output bit \( i \in \{ k + 1, k + n \} \), we have \( d(i) = c \).

From now on, we assume that all circuits that we consider satisfy these properties. Note that, since all output gates have the same depth, we can define \( d(C) = d(k + 1) \), which is the depth of all the output bits of the circuit.

Given an input bit-string \( B \in \{0, 1\}^n \), the output of each gate in \( C \) can be determined. We define \( \text{Eval}(B, i) = 1 \) if gate \( i \) is true for input \( B \), and \( \text{Eval}(B, i) = 0 \) if gate \( i \) is false for input \( B \).

Given a circuit \( C \), we define the \textit{negated form} of \( C \) to be a transformation of \( C \) in which each output bit is negated. More formally, we transform \( C \) into a circuit \( C' \) using the following operation: for each output bit \( n + i \) in \( C \), we add a \text{NOT} gate \( n + k + i \) with \( I(n + k + i) = n + i \).

3. The Construction

\textbf{Overview}. We will show that \textsc{EdgeSwitch} is \textsc{PSPACE}-complete by reducing from the circuit iteration problem \textsc{BitSwitch}. Figure 1 gives a high level picture of the construction. Given a circuit \( F \) that is to be iterated, we create a gadget that is capable of computing \( F \).
on a given input. Our construction will contain two copies of this gadget, which will be numbered 0 and 1. The two circuits alternate, with the output of one circuit being passed to the input of the other circuit. So, given an input bit-string $B$, circuit 0 computes $F(B)$, then circuit 1 computes $F(F(B))$, then circuit 0 computes $F(F(F(B)))$, and so on. The technical reason for having two copies of the circuit is that our circuit gadget cannot handle the input bits being changed before the output bits are read, and so a single circuit gadget cannot feed its own outputs back into its inputs.

Figure 1 also shows the clocks which play a fundamental role in driving the construction. Each copy of the circuit is equipped with its own clock, which controls the timing of that circuit. In particular, each clock has two states $r$ and $s$. Ordinarily, the valuation of $r$ is larger than the valuation of $s$. Every so often, the clock produces a signal, which is transmitted by the valuation of $s$ being larger than the valuation of $r$. This signal causes the associated circuit to begin computing based on its current input. Thus, the clocks play an important role in synchronising the two circuits, and ensuring that each circuit starts computing only after its partner has finished computing the previous iteration.

Each clock is implemented by a modified version of Friedmann’s exponential-time example. Friedmann’s examples are designed to force greedy all-switches strategy improvement to mimic a binary counter. The signal sent by the clock occurs when Friedmann’s example increments the binary counter to the next number. Our modifications serve only to increase the number of strategy improvement iterations that take place between each increment.

Finally, Figure 1 shows the Input/Output gadgets. These gadgets are responsible for transmitting bit-strings between the two circuits, and so they are the most complex part of the construction. These gadgets have two modes. When they are in output mode, they are connected at the outputs of a circuit, where they read and store the outputs. When they are in input mode they are connected at the inputs of the other circuit, where they allow the stored bit-string to be read. For this reason, the Input/Output gadgets must be connected to both clocks, so that they are able to transition between the circuits at the correct time.

The reduction. Formally, let $(F, B, z)$ be the input to the circuit iteration problem, and let $C$ be the negated form of the circuit that computes $F$. Throughout this section, we will use $n$ as the bit-length of $B$, and $k = |C|$ as the number of gates used in $C$. We will use OR, NOT, and INPUT/OUTPUT to denote the set of or-gates, not-gates, and input/output-gates, respectively.

In the rest of this section, we describe the construction. We begin by giving an overview of Friedmann’s example, both because it plays a key role in our construction, and because the NOT gate gadgets in our circuits are a modification of the bit-gadget used by Friedmann. We then move on to describe the gate gadgets, and how they compute the function $F$.

Priorities. As we have mentioned, the strategy improvement algorithm that we consider requires that every priority is assigned to at most one vertex. This is unfortunately a rather cumbersome requirement when designing more complex constructions. To help with this, we define a shorthand for specifying priorities. Let $c \in \mathbb{N}$, let $i, l \in \{1, \ldots, |V|\}$, let $j \in \{0, 1, 2\}$, and let $e \in \{0, 1\}$. We define

$$P(c, i, l, j, e) = 6 \cdot |V|^2 \cdot c + 6 \cdot |V| \cdot i + 6 \cdot l + 2 \cdot j + e.$$
The first four parameters should be thought of as a lexicographic ordering, which determines how large the priority is. The final number $e$ determines whether the priority is odd or even. Note that $P(c, i, l, j, e)$ is an injective function, so if we ensure that the same set of arguments are never used twice, then we will never assign the same priority to two different vertices. One thing to note is that, since this priority notation is rather cumbersome, it is not possible to use it in our diagrams. Instead, when we draw parts of the construction, we will use representative priorities, which preserve the order and parity of the priorities used in the gadgets, but not their actual values.

3.1. Friedmann’s exponential-time example. In this section, we give an overview of some important properties of Friedmann’s exponential-time examples. In particular, we focus on the properties that will be important for our construction. A more detailed description of the example can be found in Friedmann’s original paper [15].

A high level view of Friedmann’s construction is shown in Figure 2. It works by forcing greedy all-switches strategy improvement to simulate an $n$ bit binary counter. It consists of two components: a bit gadget that is used to store one of the bits of the counter, and a deceleration lane that is used to ensure that the counter correctly moves from one bit-string to the next.

The deceleration lane. Friedmann’s example contains one copy of the deceleration lane. The deceleration lane has a specified length $m$, and Figure 3 shows an example of a deceleration lane of length 4. Friedmann’s construction contains one copy of the deceleration lane of length $2n$. Remember that our diagrams use representative priorities, which preserve the order and parity of the priorities used, but not their values.

A key property of the deceleration lane is that greedy all-switches strategy improvement requires $m$ iterations to find the optimal strategy. Consider an initial strategy in which each vertex $t_i$ uses the edge to $r$, and that the valuation of $r$ is always larger than the valuation of $s$. First note that, since there is a large even priority on $t_0$, the optimal strategy is for every vertex $t_i$, with $i \geq 1$, to use the edge to $t_{i-1}$. However, since the vertices $t_i$ with $i \geq 1$ are all assigned odd priorities, in the initial strategy only the edge from $t_1$ to $t_0$ is switchable. Furthermore, once this edge has been switched, only the edge from $t_2$ to $t_1$ is switchable. In
Figure 3: Friedmann’s deceleration lane of length 4. Each $t_i$ vertex with $i > 0$ has an odd priority, while each $a_i$ vertex has an even priority that is equal to $\text{pri}(t_i) + 1$. The vertex $t_0$ has an even priority that is larger than any of the priorities assigned to the $a_i$ vertices.

In this way, the gadget ensures that $m$ iterations are required to move from the initial strategy to the optimal strategy for this gadget.

Another important property is that the gadget can be reset. This is achieved by having a single iteration in which the valuation of $s$ is much larger than the valuation of $r$, followed by another iteration in which the valuation of $r$ is much larger than the valuation of $s$. In the first iteration all vertices $t_i$ switch to $s$, and in the second iteration all vertices switch back to $r$. Note that after the second iteration, we have arrived back at the initial strategy described above.

**The bit gadget.** The bit gadget is designed to store one bit of a binary counter. The clock construction will contain $n$ copies of this gadget, which will be indexed 1 through $n$. Figure 4 gives a depiction of a bit gadget with index $i$.

The current value of the bit for index $i$ is represented by the choice that the current strategy makes at $d_i$. More precisely, for every strategy $\sigma$ we have:

- If $\sigma(d_i) = e_i$, then bit $i$ is 1 in $\sigma$.
- If $\sigma(d_i) \neq e_i$, then bit $i$ is 0 in $\sigma$.

The Odd vertex $e_i$ plays a crucial role in this gadget. If $\sigma(d_i) = e_i$, then Odd’s best response is to use edge $(e_i, h_i)$, to avoid creating the even cycle between $d_i$ and $e_i$. On the other hand, if $\sigma(d_i) \neq e_i$, then Odd’s best response is to use $(e_i, d_i)$, to avoid seeing the large even priority at $h_i$.

One thing to note is that, in the case where $\sigma(d_i) \neq e_i$, the edge to $e_i$ is always switchable. To prevent $d_i$ from immediately switching to $e_i$, we must ensure that there is always a more appealing outgoing edge from $e_i$, so that the greedy all-switches rule will switch that edge instead. The edges from $d_i$ to the deceleration lane provide this. Once $t_1$ has switched to $t_0$, the edge from $d_i$ to $a_1$ becomes more appealing than the edge to $e_i$, once $t_2$ has switched to $t_1$, the edge from $d_i$ to $a_2$ becomes more appealing than the edge to $e_i$, and so on. In this way, we are able to prevent $d_i$ from switching to $e_i$ for $2i$ iterations by providing outgoing edges to the first $2i$ vertices of the deceleration lane.
Figure 4: An example of Friedman’s bit gadget. The vertex $d_i$ has a small odd priority, while the vertex $e_i$ has an even priority that is equal to $\text{pri}(d_i) + 1$. The vertex $f_i$ has a large odd priority, while the vertex $h_i$ has a large even priority that is equal to $\text{pri}(h_i) + 1$. The priorities assigned to $k_i$ and $g_i$ are not relevant to the operation of Friedmann’s construction.

The vertices $s$ and $r$. The vertex $s$ has outgoing edges to every vertex $f_i$ in the bit gadgets, and the vertex $r$ has outgoing edges to every vertex $g_i$ in the bit gadgets. If $i$ is the index of the least significant 1 bit, then $s$ chooses the edge to $f_i$ and $r$ chooses the edge to $g_i$. The priority assigned to $r$ is larger than the priority assigned to $s$, which ensures that the valuation of $r$ is usually larger than the valuation of $s$, as required to make the deceleration lane work.

When the counter moves from one bit-string to the next, the index of the least significant 1 changes to some $i' \neq i$. The vertex $s$ switches to $f_{i'}$ one iteration before the vertex $r$ switches to $g_{i'}$. This creates the single iteration in which the valuation of $s$ is larger than the valuation of $r$, which resets the deceleration lane.

Simulating a binary counter. To simulate a binary counter, we must do two things. Firstly, we must ensure that if the counter is currently at some bit-string $K \in \{0,1\}^n$, then the least significant zero in $K$ must be flipped to a one. Secondly, once this has been done,
all bits whose index is smaller than the least significant zero must be set to 0. If these two operations are always performed, then strategy improvement will indeed count through all binary strings.

The least significant zero is always flipped because each bit $i$ has $2i$ edges to the deceleration lane. Since the purpose of the deceleration lane is to prevent the vertex $d_i$ switching to $e_i$, the vertex $d_{i'}$ where $i'$ is the index of the least significant zero, is the first to run out of edges, and subsequently switch to $e_{i'}$. Once this has occurred, all bits with index smaller than the least significant zero are set to 0 due to the following chain of events. The vertex $s$ switches $f_{i'}$, and then the vertex $d_{i''}$ in all bits with index $i'' < i'$ will be switched to $s$. Since $d_{i''}$ no longer uses the edge to $e_{i''}$, the bit has now been set to 0.

**Our modifications to Friedmann’s example.** In order to use Friedmann’s example as a clock, we make a few minor adjustments to it. Firstly, we make the deceleration lane longer. Friedmann’s example uses a deceleration lane of length $2n$, but we use a deceleration lane of length $2k + 4n + 6$. Furthermore, while the vertex $d_i$ has outgoing edges to each $a_j$ with $j \leq 2i$ in Friedmann’s version, in our modified version the vertex $d_i$ has outgoing edges to each $a_j$ with $j \leq 2i + 2k + 2n + 6$.

The reason for this is that Friedmann’s example can move from one bit-string to the next in as little as four iterations, but we need more time in order to compute the circuit $F$. By making the deceleration lane longer, we slow down the construction, and ensure that there are at least $2k + 2n + 6$ iterations before the clock moves from one bit-string to the next.

The second change that we make is to change the priorities, because we need to make room for the gadgets that we add later. However, we have not made any fundamental changes to the priorities: the ordering of priorities between the vertices and their parity is maintained. We have simply added larger gaps between them.

The following table specifies the version of the construction that we use. Observe that two copies are specified: one for $j = 0$ and the other for $j = 1$. Furthermore, observe that the vertex $x$ will be the sink in our one-sink game.

| Vertex | Conditions | Edges | Priority | Player |
|--------|------------|-------|----------|--------|
| $t_0$  | $j \in \{0, 1\}$ | $r^j$, $s^j$ | $P(2, 0, 2k + 4n + 4, j, 0)$ | Even |
| $t_i$  | $j \in \{0, 1\}$, $1 \leq i \leq 2k + 4n + 6$ | $r^j, s^j, t_{i-1}^j$ | $P(2, 0, l, j, 1)$ | Even |
| $a_j$  | $j \in \{0, 1\}$, $1 \leq l \leq 2k + 4n + 6$ | $t_i^j$ | $P(2, 0, l + 1, j, 0)$ | Even |
| $d_i$  | $j \in \{0, 1\}$, $1 \leq i \leq n$ | $e_i^l, s^j, r^j, a_i^l$ | $P(1, i, 0, j, 1)$ | Even |

The table continues with similar entries for $e_i^j$, $g_i^j$, $h_i^j$, $f_i^j$, $s^j$, $r^j$, and $x$.
3.2. Our construction.

Circuits. Given a circuit, we will produce a gadget that simulates that circuit. An example is given in Figure 5. For each gate in the circuit, we design a gadget that computes the output of that gate. The idea is that greedy all-switches strategy improvement will compute these gates in depth order. Starting from an initial strategy, the first iteration will compute the outputs for all gates of depth 1, the next iteration will use these outputs to compute the outputs for all gates of depth 2, and so on. In this way, after \( k \) iterations of strategy improvement, the outputs of the circuit will have been computed. We then use one additional iteration to store these outputs in an input/output gadget.

Strategy improvement valuations will be used to represent the output of each gate. Each gate \( i \) has a state \( o^i_j \), and the valuation of this state will indicate whether the gate evaluates to true or false. In particular the following rules will be followed.

**Property 3.1.** In every strategy \( \sigma \) we have the following properties.

1. Before the gate has been evaluated, we will have \( \text{Val}^\sigma(o^i_j) \sqsubseteq \text{Val}^\sigma(r^j) \).
2. If the gate has been evaluated to false, we will continue to have \( \text{Val}^\sigma(o^i_j) \sqsubseteq \text{Val}^\sigma(r^j) \).
3. If the gate has been evaluated to true, then we will instead have \( \text{Val}^\sigma(r^j) \sqsubseteq \text{Val}^\sigma(o^i_j) \), and \( \maxDiff^\sigma(r^j, o^i_j) \) will be a large even priority.

The input/output gadgets are connected to both circuits, and these gadgets have two modes.
(1) When circuit $j$ is computing, the gadget is in *output mode*, where it reads the output of circuit $j$ and stores it.

(2) When circuit $1-j$ is computing, the gadget is in *input mode*, where it outputs the value that was stored from the previous computation into circuit $1-j$.

Therefore, the gates of depth 1 in circuit $j$ read their input from the input/output gadgets in circuit $1-j$, while the input/output gadgets in circuit $j$ read their input from the outputs of circuit $j$. To formalise this, we introduce the following notation. For every Not-gate, we define $\text{InputState}(i,j)$ as follows:

$$\text{InputState}(i,j) = \begin{cases} o_{i(j)}^{1-j} & \text{if } d(i) = 1, \\ o_{i(i)}^j & \text{if } d(i) > 1. \end{cases}$$

For every Or-gate, and every $l \in \{1, 2\}$, we define $\text{InputState}(i,j,l)$ as follows:

$$\text{InputState}(i,j,l) = \begin{cases} o_{i(l)}^{1-j} & \text{if } d(i) = 1, \\ o_{i(l)}^j & \text{if } d(i) > 1. \end{cases}$$

**The clocks.** As we have mentioned, we use two copies of Friedmann’s example to act as clocks in our construction. These clocks will be used to drive the computation. In particular, the vertices $r^j$ and $s^j$ will play a crucial role in synchronising the two circuits. As described in the previous section, when the clock *advances*, i.e., when it moves from one bit-string to the next, there is a single iteration in which the valuation of $s^j$ is much larger than the valuation of $r^j$. This event will trigger the computation.

- The iteration in which the valuation of $s^0$ is much larger than the valuation of $r^0$ will trigger the start of computation in circuit 0.
- The iteration in which the valuation of $s^1$ is much larger than the valuation of $r^1$ will trigger the start of computation in circuit 1.

In order for this approach to work, we must ensure that the two clocks are properly synchronised. In particular, the gap between computation starting in circuit $j$ and computation starting in circuit $1-j$ must be at least $k + 3$, to give enough time for circuit $j$ to compute the output values, and for these values to be stored. We now define notation for this purpose. First we define the number of iterations that it takes for a clock to move from bit-string $K$ to $K+1$. For every bit-string $K \in \{0, 1\}^n$, we define $\text{Lsz}(K)$ to be the index of the least significant zero in $K$: that is, the smallest index $i$ such that $K^i = 0$. For each $K \in \{0, 1\}^n$, we define:

$$\text{Length}(K) = \left(2k + 2n + 6\right) + 2 \cdot \text{Lsz}(K) + 5.$$  

This term can be understood as the length of the deceleration lane to which all bits in the clock have edges, plus the number of extra iterations it takes to flip the least-significant zero, plus five extra iterations needed to transition between the two bit-strings.

Next we introduce the following delay function, which gives the amount of time each circuit spends computing. For each $j \in \{0, 1\}$ and each $K \in \{0, 1\}^n$, we define:

$$\text{Delay}(j, K) = \begin{cases} (d(C) + 3) + 2n & \text{if } j = 0, \\ (d(C) + 3) + 2 \cdot \text{Lsz}(K) + 5 & \text{if } j = 1. \end{cases}$$
Circuit 1 starts computing Delay(0, K) iterations after Circuit 0 started computing, and Circuit 0 starts computing Delay(1, K) iterations after circuit 1 started computing. Observe that Delay(0, K) + Delay(1, K) = Length(K), which ensures that the two circuits do not drift relative to each other. The term \(d(C) + 3\) in each of the delays ensures that there is always enough time to compute the circuit, before the next circuit begins the subsequent computation.

**Or gates.** The gadget for a gate \(i \in \text{OR}\) is quite simple, and is shown in Figure 6. It is not difficult to verify that the three rules given in Property 3.1 hold for this gate. Before both inputs have been evaluated, the best strategy at \(o_i^j\) is to move directly to \(r^j\), since the valuation of both inputs is lower than the valuation of \(r^j\). Note that in this configuration the valuation of \(o_i^j\) is smaller than the valuation of \(r^j\), since \(o_i^j\) has been assigned an odd priority.

Since, by assumption, both inputs have the same depth, they will both be evaluated at the same time. If they both evaluate to false, then nothing changes and the optimal strategy at \(o_i^j\) will still be \(r^j\). This satisfies the second rule. On the other hand, if at least one input evaluates to true, then the optimal strategy at \(o_i^j\) is to switch to the corresponding input states. Since the valuation of this input state is now bigger than \(r^j\), the valuation of \(o_i^j\) will also be bigger than \(r^j\), so the third rule is also satisfied.

![Figure 6: The Or gate.](image)

**Not gates.** The construction for a gate \(i \in \text{NOT}\) is more involved. The gadget is quite similar to a bit-gadget from Friedmann’s construction. However, we use a special modified deceleration lane, which is shown in Figure 7.

The modified deceleration lane is almost identical to Friedmann’s deceleration lane, except that state \(t_i^j,d_{i(d)}\) is connected to the output state of the input gate. The idea is that, for the first \(d(i) - 1\) iterations the deceleration lane behaves as normal. Then, in iteration \(d(i)\), the input gate is evaluated. If it evaluates to true then the valuation of \(t_i^j,d_{i(d)}\) will be large, and the deceleration lane continues switching as normal. If it evaluates to false, then the valuation of \(t_i^j,d_{i(d)}\) will be low, and the deceleration lane will stop switching.
The $\text{Not}$ gate gadget, which is shown in Figure 8 is a simplified bit gadget that is connected to the modified deceleration lane. As in Friedmann’s construction, the strategy chosen at $d^j_i$ will represent the output of the gate. In a strategy $\sigma$, the gate outputs 1 if $\sigma(d^j_i) = e^j_i$, and it outputs 0 otherwise. As we know, Friedmann’s bit gadget is distracted from switching $d^j_i$ to $e^j_i$ by the deceleration lane. By using the modified deceleration lane, we instead obtain a $\text{Not}$ gate. Since the deceleration lane keeps on switching if and only if the input gate evaluates to true, the state $d^j_i$ will switch to $e^j_i$ in iteration $d(i)$ if and only if the input gate evaluates to false. This is the key property that makes the $\text{Not}$ gate work.

To see that the three rules specified in Property 3.1 are respected, observe that there is a large odd priority on the state $o^j_i$, and an even larger even priority on the state $h^j_i$. This

![Figure 7: Modified deceleration lane for a $\text{Not}$ gate $i$ in circuit $j$.](image)

![Figure 8: $\text{Not}$ gate with index $i$ in circuit $j$.](image)
causes the valuation of $o^j_i$ to only be larger than the valuation of $r^j_i$ if and only if $d^j_i$ chooses the edge to $e^j_t$, which only happens when the gate evaluates to true.

Finally, when the computation in circuit $j$ begins again, the Not-gate is reset. This is ensured by giving the vertex $d^j_i$ edges to both $s^j_i$ and $r^j_i$. So, when the clock for circuit $j$ advances, no matter what strategy is currently chosen, the vertex $d^j_i$ first switches to $s^j_i$, and then to $r^j_i$, and then begins switching to the deceleration lane.

The following table formally specifies the Not gate gadgets that we use in the construction.

| Vertex     | Conditions                              | Edges          | Priority                                                                 | Player |
|------------|-----------------------------------------|----------------|---------------------------------------------------------------------------|--------|
| $r^j_{i,0}$| $j \in \{0,1\}, i \in \text{Not}$     | $r^j_i, s^j_i$ | P(5, i, 2k + 4n + 4, j, 0)                                               | Even   |
| $r^j_{i,l}$| $j \in \{0,1\}, i \in \text{Not}$     | $r^j_i, s^j_i, t^j_{i,l-1}$ | P(5, i, l, j, 1)                                                        | Even   |
| $t^j_{i,d(i)}$| $j \in \{0,1\}, i \in \text{Not}$, $1 \leq l \leq 2k + 4n + 6$, and $l \neq d(i)$ | InputState$(i, j)$ | P(5, i, d(i), j, 1)                                                      | Even   |
| $a^j_{i,l}$| $j \in \{0,1\}, i \in \text{Not}$     | $t^j_{i,l}$    | P(5, i, l + 1, j, 0)                                                     | Even   |
| $a^j_{i,d(i)}$| $j \in \{0,1\}, i \in \text{Not}$, $1 \leq l \leq 2k + 4n + 6$, and $l \neq d(i)$ | $t^j_{i,d(i)}$  | P(4, i, 0, j, 0)                                                        | Even   |
| $d^j_i$    | $j \in \{0,1\}, i \in \text{Not}$     | $s^j_i, r^j_i, e^j_i, a^j_{i,l}$ for $1 \leq l \leq 2k + 4n + 6$ | P(4, i, 0, j, 1)                                                        | Even   |
| $e^j_i$    | $j \in \{0,1\}, i \in \text{Not}$     | $h^j_{i}, d^j_i$| P(4, i, 1, j, 0)                                                         | Odd    |

Input/output gates. For each input-bit in each copy of the circuit, have an input/output gate. Recall that these gadgets have two modes. When Circuit $j$ is computing, the input/output gadgets in circuit $j$ are in output mode, in which they store the output of the circuit, and the input/output gadgets in circuit $1 - j$ are in input mode, in which they output the value that was stored in the previous computation.

At its core, the input/output gadget is simply another copy of the Not-gate gadget that is connected to the $i$th output bit of circuit $j$. However, we modify the Not-gate gadget by adding in extra vertices that allow it to be moved between the two circuits. The most important part of this circuit mover apparatus is shown in Figure 9: all of the vertices in the Not-gate gadget that have edges to $r^j$ and $s^j$ are modified so that they instead have edges to $y^j$ and $z^j$. Figures 10 and 11 show the Input/Output gadget and its associated modified deceleration lane, respectively. There are three differences between this gadget and the Not gate, which are the inclusion of the vertices $h^j_{i,0}$ and $q^j_{i,1}$ (shown in Figure 10), and the vertices $p^j_i$ and $p^j_{i,1}$ (shown in Figure 11). All of these vertices are involved in the operation of moving the gadget between the two circuits.

When the gadget is in output mode, the vertex $y^j$ chooses the edge to $r^j$, the vertex $h^j_{i,0}$ chooses the edge to $h^j_{i,1}$, and the vertex $p^j_i$ chooses the edge to $o^j_{i(i)}$. When these edges are chosen, the gadget is essentially the same as a Not-gate at the top of the circuit. So, once the circuit has finished computing, the vertex $d^j_i$ chooses the edge to $e^j_i$ (i.e., the stored bit is 1) if and only if the $i$th output from the circuit was a 0. Since the circuit was given in negated form, the gadget has therefore correctly stored the $i$th bit of $F(B)$.
Throughout the computation in circuit $j$, the valuation of $r^j$ is much larger than the valuation of $r^{1-j}$. The computation in circuit $1-j$ begins when the clock in circuit $1-j$ advances, which causes the valuation of $r^{1-j}$ to become much larger than the valuation of $r^j$. When this occurs, the input/output gate then transitions to input mode. The transition involves the vertex $y^j$ switching to $r^{1-j}$, the vertex $h^j_{i,0}$ switching to $h^j_{i,2}$, and the vertex $p^j_i$ switching to $p^j_{i,1}$. Moreover, the player Odd vertex $q^j_{i,0}$ switches $e^j_i$. This vertex acts as a circuit breaker, which makes sure that the output of the gadget is only transmitted to circuit $1-j$ when the gadget is in input mode.

The key thing is that all of these switches occur simultaneously in the same iteration. Since strategy improvement only cares about the relative difference between the outgoing edges from the vertex, and since all edges leaving the gadget switch at the same time, the operation of the Not-gate is not interrupted. So, the strategy chosen at $d^j$ will continue to hold the $i$th bit of $F(B)$, and the gadget has transitioned to input mode.

When the gadget is in input mode, it can be viewed as a Not at the bottom of circuit $1-j$ that has already been computed. In particular, the switch from $h^j_{i,1}$ to $h^j_{i,2}$ ensures that, if the output is 1, then the gadget has the correct output priority. Moreover, the deceleration lane has enough states to ensure that, if the output is 0, then output of the gadget will not flip from 0 to 1 while circuit $1-j$ is computing.

Finally, once circuit $1-j$ has finished computing, the clock for circuit $j$ advances, and the input/output gadget moves back to output mode. This involves resetting the Not gate gadget back to its initial state. This occurs because, when the clock in circuit $j$ advances, there is a single iteration in which the valuation of $s^j$ is higher than the valuation of $r^j$. This causes $z^j$ to switch to $s^j$ which in turn causes a single iteration in which the valuation of $z^j$ is higher than the valuation of $y^j$. Then, in the next iteration the vertex $y^j$ switches to $r^j$, and so the valuation of $y^j$ is then larger than the valuation of $z^j$. So, the valuations of
$y^j$ and $z^j$ give exactly the same sequence of events as $r^j$ and $s^j$, which allows the Not-gate to reset.

The following table specifies the input/output gadget.

| Vertex  | Conditions                      | Edges                                | Priority                        | Player |
|---------|---------------------------------|--------------------------------------|---------------------------------|--------|
| $y^j$   | $j \in \{0, 1\}$               | $r^{1-j}, r^j$                       | $P(3, 0, 1, j, 0)$              | Even   |
| $z^j$   | $j \in \{0, 1\}$               | $r^j, s^j$                           | $P(3, 0, 0, 0, 0)$              | Even   |
| $t_{i,0}^j$ | $j \in \{0, 1\}, i \in INPUT/OUTPUT$ | $y^j, z^j$                           | $P(5, i, 2k + 4n + 4, j, 0)$    | Even   |
| $t_{i,l}^j$ | $j \in \{0, 1\}, i \in INPUT/OUTPUT,$ | $y^j, z^j, t_{i,l-1}^j$ | $P(5, i, l, j, 1)$              | Even   |
| $t_{i,d(C)}^j$ | $j \in \{0, 1\}, i \in INPUT/OUTPUT,$ | $p_i^j$ | $P(5, i, d(C), j, 1)$              | Even   |
| $p_i^j$ | $j \in \{0, 1\}, i \in INPUT/OUTPUT$ | $h_{i,0}^j, d_{i,l}^j$ for $1 \leq l \leq 2k + 4n + 6$ | $P(4, i, 0, 0, 1)$              | Even   |
| $q_{i,0}^j$ | $j \in \{0, 1\}, i \in INPUT/OUTPUT$ | $e_{i,0}^j, q_{i,0}^j$ | $P(4, i, 1, j, 0)$              | Odd    |
| $q_{i,1}^j$ | $j \in \{0, 1\}, i \in INPUT/OUTPUT$ | $r_{i,j}^j$ | $P(6, d(C) + 2, 0, j, 0)$              | Even   |
| $a_{i,j}^j$ | $j \in \{0, 1\}, i \in INPUT/OUTPUT,$ | $h_{i,0}^j$ | $P(6, i, 0, 0, 1)$              | Even   |
| $b_{i,0}^j$ | $j \in \{0, 1\}, i \in INPUT/OUTPUT$ | $h_{i,1}^j, h_{i,2}^j$ | $P(3, i, 3, j, 0)$              | Even   |
| $b_{i,1}^j$ | $j \in \{0, 1\}, i \in INPUT/OUTPUT$ | $r^j$ | $P(6, d(C) + 1, 1, j, 0)$              | Even   |
| $b_{i,2}^j$ | $j \in \{0, 1\}, i \in INPUT/OUTPUT,$ | $r^{1-j}$ | $P(6, 0, 1, j, 0)$              | Even   |

**One-sink game.** If we are to use the simplified strategy improvement algorithm, we must first show that this construction is a one-sink game. We do so in the following lemma.

**Lemma 3.2.** The construction is a one-sink game.

**Proof.** In order to show that the construction is a one-sink game, we must show that the two required properties hold. Firstly, we must show that there is a vertex the satisfies the required properties of a sink vertex. It is not difficult to verify that vertex $x$ does indeed satisfy these properties: the only outgoing edge from $x$ is the edge $(x, x)$, and we have $\text{pri}(x) = P(0, 0, 0, 0, 0) = 1$. Furthermore, no vertex is assigned priority 0.

Secondly, we must argue that all optimal strategies are terminating. Recall that a terminating strategy has the property that the first component of the V"oge-Jurdziński valuation is 1, which implies that all paths starting at all vertices eventually arrive at the sink $x$. So, consider a strategy $\sigma$ that is not terminating, and let $v$ be a vertex such that the first component of $\text{Val}_v^{\sigma}$ is strictly greater than 1. Let $C$ be the cycle that is eventually reached by following $\sigma$ and $\text{Br}(\sigma)$ from $v$. There are two cases to consider:

- If $C$ contains at least one vertex from a clock, then $C$ must be entirely contained within that clock, because there are no edges that leave either of the two clocks. In this case we have that $\sigma$ is not optimal because Friedmann has shown that his construction is a one-sink game.
- If $C$ does not contain a vertex from a clock, then it is entirely contained within the circuits. First observe that $C$ cannot be a two-vertex cycle using the vertices $d_i^j$ and $c_i^j$, because
it is not a best-response for Odd allow a cycle with an even priority to be formed, since he can always move to $r^j$, and from there eventually reach a cycle with priority $p \leq 1$ (because the clock is a one-sink game). But, the only other way to form a cycle in the circuits is to pass through both of the circuits. In this case, the highest priority on the cycle will be an odd priority assigned to the state $o^j$ in either a $\text{Not}$-gate (if there is one on the path), or an input/output gate (otherwise). Since this odd priority is strictly greater than 1, and since player Even can always assure a priority of 1 by, for example, moving to $r^j$ in every input/output state $d^j$, we have that $\sigma$ is not an optimal strategy. Therefore, we have shown that the construction is a one-sink game.

4. Strategies

In this section, we define an initial strategy, and describe the sequence of strategies that greedy all-switches strategy improvement switches through when it is applied to this initial strategy. We will define strategies for each of the gadgets in turn, and then combine these into a full strategy for the entire construction.

It should be noted that we will only define partial strategies in this section, which means that some states will have no strategy specified. This is because our construction will work no matter which strategy is chosen at these states.

To deal with this, we must define what it means to apply strategy improvement to a partial strategy. If $\chi$ is a partial strategy and $\sigma \in \Sigma_{\text{Even}}$ is a strategy, then we say that $\sigma$ agrees with $\chi$ if $\sigma(v) = \chi(v)$ for every vertex $v \in V$ for which $\chi$ is defined. So, if $\chi_1$ and $\chi_2$ are partial strategies, then we say that greedy all-switches strategy improvement switches $\chi_1$ to $\chi_2$ if, for every strategy $\sigma_1 \in \Sigma_{\text{Even}}$ that agrees with $\chi_1$, greedy all-switches strategy improvement switches $\sigma_1$ to a strategy $\sigma_2$ that agrees with $\chi_2$.

We now describe the sequence of strategies. Each part of the construction will be considered independently.

The clock. We start by defining the sequence of strategies that occurs in the two clocks. For each clock bit-string $K \in \{0, 1\}^n$, we define a sequence of strategies $\kappa^K_1, \kappa^K_2, \ldots, \kappa^K_{\text{Length}(K)}$. Greedy all-switches strategy improvement switches through each of these strategies in turn, and then switches from $\kappa^K_{\text{Length}(K)}$ to $\kappa^{K+1}_1$, where $K + 1$ denotes the bit-string that results by adding 1 to the integer represented by $K$. The sequence begins in the first iteration after the valuation of $s^j$ is larger than the valuation of $r^j$. We will first present the building blocks of this strategy, and then combine the building blocks into the full sequence.

We begin by considering the vertices $t^j_i$ in the deceleration lane. Recall that these states switch, in sequence, from $r^j$ to $t^j_{i-1}$. This is formalised in the following definition. For each $m \geq 1$, each $l$ in the range $1 \leq l \leq 2k + 4n + 6$, and each $j \in \{0, 1\}$, we define:

$$\rho_m(t^j_0) = \begin{cases} s^j & \text{if } m = 1, \\ r^j & \text{if } m > 1. \end{cases}$$

$$\rho_m(t^j_i) = \begin{cases} s^j & \text{if } m = 1, \\ r^j & \text{if } m > 1 \text{ and } m \leq l + 1, \\ t^j_{i-1} & \text{if } m > l + 1. \end{cases}$$
We now move on to consider the vertices \(d_{ji}^j\), which represent the bits in the counter. We begin by defining a sequence of strategies for the bits that are 0. Recall that these vertices switch to the states \(a_{ji}^j\) along the deceleration lane until they run out of edges, at which point they switch to the vertex \(e_{ji}^j\). This is formalised in the following definition. For each \(i\) in the range \(1 \leq i \leq n\), each \(m \geq 1\), and each \(j \in \{0, 1\}\), we define:

\[
\rho_m(d_{ji}^j) = \begin{cases} 
  s_{ji}^j & \text{if } m = 1, \\
  r_{ji}^j & \text{if } m = 2, \\
  a_{2k+2n+6+2i}^j & \text{if } m = 3, \\
  a_{m-3}^j & \text{if } 4 \leq m \leq 2k + 2n + 6 + 2i + 3, \\
  e_{ji}^j & \text{if } m > 2k + 2n + 6 + 2i + 3.
\end{cases}
\]

Note that the first three iterations are special, because the edge to \(a_{ji}^1\) only becomes switchable in the third iteration. The edge to \(r_{ji}^j\) and the edge to \(a_{2k+2n+6+2i}^j\) prevent the edge to \(e_{ji}^j\) being switched before this occurs.

We now give a full strategy definition for the vertices \(d_{ji}^j\). The bits that are 0 follow the strategy that we just defined, and the bits that are 1 always choose the edge to \(e_{ji}^j\). For each bit-string \(K \in \{0, 1\}^n\), each \(i\) in the range \(1 \leq i \leq n\), each \(m \geq 1\), and each \(j \in \{0, 1\}\), we define:

\[
\rho^K_m(d_{ji}^j) = \begin{cases} 
  \rho_m(d_{ji}^j) & \text{if } K_i = 0, \\
  e_{ji}^j & \text{if } K_i = 1.
\end{cases}
\]

Finally, we consider the other vertices in the clock. To define strategies for these vertices, we must first define some notation. For each \(i\) in the range \(1 \leq i \leq n\), we define \(\text{NextBit}(K, i)\) to be a partial function that gives the index of the first 1 that appears higher than index \(i\): that is, the smallest index \(j > i\) such that \(K_j = 1\). We now define the strategies. These strategies all depend on the current clock bit-string \(K\), and have no dependence on how far the deceleration lane has switched, so the parameter \(m\) is ignored. For each bit-string \(K \in \{0, 1\}^n\), each \(m \geq 1\), each \(i\) in the range \(1 \leq i \leq n\), and each \(j \in \{0, 1\}\), we define:

\[
\rho^K_m(g_{ji}^j) = \begin{cases} 
  k_{ji}^j & \text{if } K_i = 0, \\
  f_{ji}^j & \text{if } K_i = 1.
\end{cases}
\]

\[
\rho^K_m(k_{ji}^j) = \begin{cases} 
  g_{\text{NextBit}(K, i)}^j & \text{if NextBit}(K, i) \text{ is defined}, \\
  x & \text{otherwise}.
\end{cases}
\]

\[
\rho^K_m(r_{ji}^j) = \begin{cases} 
  g_{\text{NextBit}(K, 0)}^j & \text{if NextBit}(K, 0) \text{ is defined}, \\
  x & \text{otherwise}.
\end{cases}
\]

\[
\rho^K_m(s_{ji}^j) = \begin{cases} 
  f_{\text{NextBit}(K, 0)}^j & \text{if NextBit}(K, 0) \text{ is defined}, \\
  x & \text{otherwise}.
\end{cases}
\]

When the clock transitions between two clock bit-strings, there is a single iteration in which the strategies defined above are not followed. This occurs one iteration after the vertex \(d_{Lsz(K)}^j\) switches to \(e_{Lsz(K)}^j\). In this iteration, the vertices \(g_{Lsz(K)}^j\) and \(s_{Lsz(K)}^j\) switch to \(f_{Lsz(K)}^j\), while every other vertex continues to use the strategies that were defined above. We now define a special \textit{reset strategy} that captures this. For each bit-string \(K \in \{0, 1\}^n\), and
every vertex \( v \) in either of the two clocks we define:

\[
\rho^K_{\text{Reset}}(v) = \begin{cases} 
  f^j_{\text{Lsz}(K)}(v) & \text{if } v = g^j_{\text{Lsz}(K)} \text{ or } v = s^j, \\
  \rho^K_{\text{Length}(K)}(v) & \text{otherwise}.
\end{cases}
\]

We can now combine the strategies defined above in order to define the full sequence of strategies that are used in the clocks. In the first \( \text{Length}(K) - 1 \) iterations, we follow the sequence defined by the strategies \( \rho^K_m(v) \), and in the final iteration we use the strategy \( \rho^K_{\text{Reset}}(v) \). Formally, for each bit-string \( K \in \{0, 1\}^n \), each \( m \) in the range \( 1 \leq m \leq \text{Length}(K) \), and every vertex \( v \) in either of the two clocks, we define:

\[
\kappa^K_m(v) = \begin{cases} 
  \rho^K_m(v) & \text{if } m \leq \text{Length}(K) - 1, \\
  \rho^K_{\text{Reset}}(v) & \text{if } m = \text{Length}(K).
\end{cases}
\]

Friedmann showed the following lemma.

**Lemma 4.1** ([15]). *Let \( K \in \{0, 1\}^n \). If we start all-switches strategy improvement at \( \kappa^K_1 \) for clock \( j \), then it will proceed by switching through the sequence \( \kappa^K_1, \kappa^K_2, \ldots, \kappa^K_{\text{Length}(K)}, \kappa^K_{\text{Length}(K)+1} \).*

The circuits. For each bit-string \( B \in \{0, 1\}^n \), we give a sequence of strategies \( \sigma^B_1, \sigma^B_2, \ldots \), which describes the sequence of strategies that occurs when \( B \) is the input of the circuit. The sequence is indexed from the point at which the circuit’s clock advances to the next bit-string. That is, \( \sigma^B_1 \) occurs one iteration after the valuation of \( s^j \) exceeds the valuation of \( r^j \).

Recall that all of the gates with the same depth are evaluated in the same iteration. We can now make this more precise: each gate \( i \) will be evaluated in the strategy \( \sigma^B_{d(i)+2} \). After this iteration, there will then be two cases based on whether the gate evaluates to 1 or 0. To deal with this, we require the following notation. For each bit-string \( B \) and each gate \( i \), we define \( \text{Eval}(B, i) \) to be 1 if gate \( i \) outputs true on input \( B \), and 0 otherwise.

Or gates. Before the gate is evaluated, the state \( o^j_i \) chooses the edge to \( r^j \). Once the gate has been evaluated, there are four possibilities. If both input gates evaluate to false, then the state \( o^j_i \) continues to use the edge to \( r^j \). If one of the two inputs is true, then \( o^j_i \) will switch to the corresponding input state. The case where both inputs are true is the most complicated. Obviously, \( o^j_i \) will switch to one of the two input states, and in fact, it switches to the one with the highest valuation. Since the overall correctness of our construction does not care which successor is chosen in this case, we simply define \( \text{OrNext}(i, B, m) \) to be the successor with the highest valuation in step \( m \) of the sequence for bit-string \( B \).

We can now formally define the sequence of strategies used by an Or-gate. For every gate \( i \in \text{Or} \), every pair of bit-strings \( B \in \{0, 1\}^n \), and every \( m \geq 1 \) we define:

\[
\sigma^B_m(o^j_i) = \begin{cases} 
  s^j_i & \text{if } m = 1, \\
  r^j_i & \text{if } m > 1 \text{ and } m \leq d(i) + 2, \\
  r^j_i & \text{if } m > d(i) + 2 \text{ and } \text{Eval}(B, I_1(i)) = 0 \text{ and } \text{Eval}(B, I_2(i)) = 0, \\
  \text{InputState}(i, j, 1) & \text{if } m > d(i) + 2 \text{ and } \text{Eval}(B, I_1(i)) = 1 \text{ and } \text{Eval}(B, I_2(i)) = 0, \\
  \text{InputState}(i, j, 2) & \text{if } m > d(i) + 2 \text{ and } \text{Eval}(B, I_1(i)) = 0 \text{ and } \text{Eval}(B, I_2(i)) = 1, \\
  \text{OrNext}(i, B, m) & \text{if } m > d(i) + 2 \text{ and } \text{Eval}(B, I_1(i)) = 1 \text{ and } \text{Eval}(B, I_2(i)) = 1.
\end{cases}
\]
Not gates. There are two components of the Not-gate gadget: the modified deceleration lane and the state $d_{i}$. We begin by considering the modified deceleration lane.

We first define a strategy for the case where the gate evaluates to false. In this case, the input gate evaluates to true, which causes the modified deceleration lane to continue switching after iteration $d(i) + 2$. We formalise this in the following definition, which is almost identical to the definition given for the deceleration lane used in the clock. For each $i \in \text{Not}$, each $l$ in the range $1 \leq l \leq 2k + 4n + 6$ with $l \neq d(i)$, each $j \in \{0, 1\}$, and each $m \geq 1$, we define:

$$
\sigma_{m}(t_{i,l}^{j}) = \begin{cases} 
  s_{j} & \text{if } m = 1, \\
  r_{j} & \text{if } m > 1.
\end{cases}
$$

(4.2)

$$
\sigma_{m}(t_{i,l}^{j}) = \begin{cases} 
  s_{j} & \text{if } m = 1, \\
  r_{j} & \text{if } m > 1 \text{ and } m \leq l + 1, \\
  t_{i,l-1}^{j} & \text{if } m > l + 1.
\end{cases}
$$

(4.3)

On the other hand, if the gate evaluates to false, then the deceleration lane stops switching. This is formalised in the following definition, which uses the previous definition to give the actual strategy used by the modified deceleration lane. For each $i \in \text{Not}$, each $B \in \{0, 1\}^{n}$, each $l$ in the range $0 \leq l \leq 2k + 4n + 6$ with $l \neq d(i)$, each $j \in \{0, 1\}$, and each $m \geq 1$, we define:

$$
\sigma_{B,m}(t_{i,l}^{j}) = \begin{cases} 
  \sigma_{m}(t_{i,l}^{j}) & \text{if } l \leq d(i) + 1, \text{ or } l > d(i) + 1 \text{ and } \text{Eval}(B, I(i)) = 1, \\
  s_{j} & \text{if } l > d(i) + 1 \text{ and } m = 1 \text{ and } \text{Eval}(B, I(i)) = 0, \\
  r_{j} & \text{if } l > d(i) + 1 \text{ and } m > 1 \text{ and } \text{Eval}(B, I(i)) = 0.
\end{cases}
$$

(4.4)

We now turn out attention to the state $d_{i}$, where we again begin by considering the case where the gate evaluates to false. In this case, the state $d_{i}$ continues switching to the modified deceleration lane. This is formalised in the following definition, which is almost identical to the definition given for the corresponding states in the clock. For all $i \in \text{Not} \cup \text{Input/Output}$, all $B \in \{0, 1\}^{n}$, for all $m \geq 1$, and all $j \in \{0, 1\}$, we define:

$$
\sigma_{m}(d_{i}^{j}) = \begin{cases} 
  s_{j} & \text{if } m = 1, \\
  r_{j} & \text{if } m = 2, \\
  a_{i,2k+4n+6}^{j} & \text{if } m = 3, \\
  a_{i,m-3}^{j} & \text{if } 4 \leq m \leq 2k + 4n + 6 + 3, \\
  c_{i}^{j} & \text{if } 2k + 4n + 6 + 3 < m.
\end{cases}
$$

On the other hand, if the gate evaluates to true, then after iteration $d(i) + 2$, the state $d_{i}$ switches to $c_{i}^{j}$. This is formalised in the following definition, where the previous definition is used in order to give the actual sequence of strategies for the state $d_{i}$. For all $B \in \{0, 1\}^{n}$, all $i \in \text{Not}$, all $j \in \{0, 1\}$, and all $m \geq 1$ we define:

$$
\sigma_{B,m}(d_{i}^{j}) = \begin{cases} 
  \sigma_{m}(d_{i}^{j}) & \text{if } m \leq d(i) + 2, \text{ or } m > d(i) + 2 \text{ and } \text{Eval}(B, I(i)) = 1, \\
  c_{i}^{j} & \text{if } m > d(i) + 2 \text{ and } \text{Eval}(B, I(i)) = 0.
\end{cases}
$$

(4.4)
Input/output gates. We now describe the sequence of strategies used in the input/output gates. These strategies are almost identical to the strategies that would be used in a Not-gates with depth \(d(C) + 1\), but with a few key differences. Firstly, whereas the Not-gates used edges to \(r^j\) and \(s^j\), these have instead been replaced with the edges to \(y^j\) and \(z^j\) from the circuit movers. Secondly, the circuit movers cause a one iteration delay at the start of the sequence. Note, however, that despite this delay, the input/output gates are still evaluated on iteration \(d(C) + 3\).

We begin by giving the strategies for the modified deceleration lane used in the input/output gates. For each \(i \in \text{Not}\), each \(l\) in the range \(1 \leq l \leq 2k + 4n + 6\) with \(l \neq d(C)\), each \(j \in \{0, 1\}\), and each \(m \geq 1\), we define:

\[
\sigma_m(t^j_{i,l}) = \begin{cases} 
  z^j & \text{if } m = 2, \\
  y^j & \text{if } m = 1 \text{ or } m > 1 \text{ and } m \leq l + 2, \\
  t^j_{i,l-1} & \text{if } m > l + 2.
\end{cases}
\]

\[
\sigma_m(t^j_{i,0}) = \begin{cases} 
  z^j & \text{if } m = 2, \\
  y^j & \text{if } m = 1 \text{ or } m > 2.
\end{cases}
\]

Then, for each \(i \in \text{Not}\), each \(B \in \{0, 1\}^n\), each \(l\) in the range \(0 \leq l \leq 2k + 4n + 6\) with \(l \neq d(C)\), each \(j \in \{0, 1\}\), and each \(m \geq 1\), we define:

\[
\sigma^B_m(t^j_{i,l}) = \begin{cases} 
  \sigma_m(t^j_{i,l}) & \text{if } l < d(C) + 3, \text{ or } l \geq d(C) + 3 \text{ and } B_i = 0, \\
  z^j & \text{if } l > d(C) + 3 \text{ and } m = 2 \text{ and } B_i = 1, \\
  y^j & \text{if } l > d(C) + 3 \text{ and either } m = 1 \text{ or } m > 2 \text{ and } B_i = 1.
\end{cases}
\]

Finally, we give the strategy for the state \(d^j_i\). We reuse the strategy \(\sigma_{m-1}\) from the Not-gate definitions, but with a one iteration delay. For all \(B \in \{0, 1\}^n\), all \(i \in \text{Input/Output}\), all \(j \in \{0, 1\}\), and all \(m > 1\) we define:

\[
\sigma^B_m(d^j_i) = \begin{cases} 
  \sigma_{m-1}(d^j_i) & \text{if } 1 < m \leq d(C) + 3, \text{ or } m > d(C) + 3 \text{ and } B_i = 0, \\
  e^j & \text{if } m > d(i) + 3 \text{ and } B_i = 1.
\end{cases}
\]

The circuit mover states. Finally, we describe the sequence of strategies used in the states that move the input/output gates between the circuits. These strategies do not depend on the current input bit-string to the circuit. Instead, they depend on the state of both of the clocks, and are parameterized by the value of the delay function that we defined earlier.
Formally, for every $m \geq 1$, every $i \in \text{Input/Output}$, and every clock-bit string $K \in \{0,1\}^n$ we define:

\[
\sigma^K_m(z^j) = \begin{cases} s^j & \text{if } m = 1, \\ r^j & \text{if } m > 1. \end{cases} \tag{4.6}
\]

\[
\sigma^K_m(y^j) = \begin{cases} r^{1-j} & \text{if } m = 1 \text{ or } m \geq \text{Delay}(j,K) + 1, \\ r^j & \text{if } m > 1 \text{ and } m < \text{Delay}(j,K) + 1. \end{cases} \tag{4.7}
\]

\[
\sigma^K_m(p^j_i) = \begin{cases} p^j_i & \text{if } m = 1 \text{ or } m \geq \text{Delay}(j,K) + 1, \\ o^j_{I(i)} & \text{if } 1 < m \leq \text{Delay}(j,K) + 1. \end{cases} \tag{4.8}
\]

\[
\sigma^K_m(h^j_{i,0}) = \begin{cases} h^j_{i,2} & \text{if } m = 1 \text{ or } m \geq \text{Delay}(j,K) + 1, \\ h^j_{i,1} & \text{if } 1 < m < \text{Delay}(j,K) + 1. \end{cases} \tag{4.9}
\]

Putting it all together. We can now define a combined sequence of strategies for the entire construction. We will define a sequence of strategies $\chi^{B,K,j}_1, \chi^{B,K,j}_2, \ldots$, which describes a computation in circuit $j$ under the following conditions:

- The clock for circuit $j$ currently stores $K$ in its binary counter.
- The input to circuit $j$ is $B$.

Before stating the strategies, we first define some necessary notation. For every clock-bit-string $K \in \{0,1\}$, and every $j \in \{0,1\}$ we define:

\[
\text{OC}(K,j) = \begin{cases} K - 1 & \text{if } j = 0, \\ K & \text{if } j = 1. \end{cases}
\]

This gives the bit-string used in the other clock, when circuit $j$ is computing. Since clock 0 is ahead of clock 1, we have that $\text{OC}(K,0)$ is the bit-string before $K$, while $\text{OC}(K,1)$ is the same as $K$.

We can now define the sequence. For each bit-string $B \in \{0,1\}^n$, each bit-string $K \in \{0,1\}^n$, each $m \geq 1$, and every vertex $v$ we define:

\[
\chi^{B,K,j}_m(v) = \begin{cases} \kappa^K_m(v) & \text{if } v \text{ is in clock } j, \\ \kappa_m^{\text{OC}(K,j)}(v) & \text{if } v \text{ is in clock } 1 - j, \\ \sigma^K_m(v) & \text{if } v \text{ is in a NOT or OR gate in circuit } j, \\ \sigma^{\text{OC}(K,j)}_m(v) & \text{if } v \text{ is in an input/output gate in circuit } j, \\ \sigma^{B,\text{Delay}(1-j,\text{OC}(K,j))}_m(v) & \text{if } v \text{ is an input/output gate in circuit } 1 - j, \\ \sigma^K_m(v) & \text{if } v \text{ is a circuit mover state in circuit } j, \\ \sigma^{\text{OC}(K,j)}_m(v) & \text{if } v \text{ is a circuit mover state in circuit } 1 - j. \end{cases}
\]

The first two cases of this definition deal with the clocks: the clock in circuit $j$ follows the sequence for bit-string $K$, while the clock in circuit $1 - j$ continues to follow the sequence for bit-string $\text{OC}(K,j)$. Observe that the clock for circuit $1 - j$ has already been running for $\text{Delay}(1 - j, \text{OC}(K,j))$ iterations, so the strategies for this clock start on iteration $1 + \text{Delay}(1 - j, \text{OC}(K,j))$. The next two cases deal with the gate gadgets in circuit $j$: the NOT and OR gates follow the sequence for bit-string $B$, and then the input/output gates for
circuit \( j \), which are in output mode, store \( F(B) \). The next case deals with the input/output gates in circuit \( 1 - j \) are in input mode, and so follow the strategy for bit-string \( B \). The final two cases deal with the circuit mover states, which follow the strategies for the clock bit-string used in their respective clocks. Observe that no strategy is specified for the gate gadgets in circuit \( 1 - j \), because the strategy chosen here is irrelevant.

For technical convenience, we define:

\[
\chi_{\text{Delay}(0,K)}^{B,K,0}(B,K) = \chi_1^{F(B),K,1} \\
\chi_{\text{Delay}(1,K)}^{B,K,1}(B,K) = \chi_1^{F(B),K+1,0}
\]

Using this definition, we can now state the main technical claim of the paper.

**Lemma 4.2.** Let \( B \in \{0,1\}^n \) be a bit-string, let \( C \in \{0,1\}^n \) be a bit-string such that \( C \neq (1,1,\ldots,1) \), and let \( j \in \{0,1\} \). If greedy all-switches strategy improvement is applied to \( \chi_1^{B,K,0} \), then it will pass through the sequence:

\[
\chi_1^{B,K,j}, \chi_2^{B,K,j}, \ldots, \chi_{\text{Delay}(j,K)}^{B,K,j}.
\]

Unfortunately, the proof of this lemma is quite long, and the vast majority of it is presented in the appendix. In Section 5, we give an overview of the proof, and describe how each of the individual appendices fit into the overall proof.

**Best responses.** Recall that, for each strategy considered, strategy improvement computes a best-response for the opponent. Now that we have defined the sequence of strategies, we can also define the best-responses to these strategies. For each strategy \( \chi_i^{B,K,j} \), we define a strategy \( \mu_i^{B,K,j} \in \Sigma_{\text{Odd}} \) that is a best-response to \( \chi_i^{B,K,j} \). We will later prove that these strategies are indeed best-responses.

We begin by considering the vertices \( e_i^j \) for each \( \text{Not} \)-gate \( i \). Recall that these vertices only pick the edge to \( h_i^j \) in the case where they are forced to by \( d_i^j \) selecting the edge to \( e_i^j \). As defined above, this only occurs in the case where the \( \text{Not} \)-gate evaluates to true. Formally, for each bit-string \( B \in \{0,1\}^n \), each bit-string \( K \in \{0,1\}^n \), each \( m \geq 1 \), and every vertex \( i \in \text{Not} \) we define:

\[
\mu_m^{B,K,j}(e_i^j) = \begin{cases} 
    h_i^j & \text{if } m > d(i) + 2 \text{ and } \text{Eval}(B,I(i)) = 0, \\
    d_i^j & \text{otherwise}.
\end{cases}
\]

For the input/output gadgets in circuit \( 1 - j \), which will provide the input to circuit \( j \), the situation is the same. The vertex \( e_i^{1-j} \) chooses the edge to \( h_i^{1-j} \) if and only if \( B_i \) is 1. Formally, for each bit-string \( B \in \{0,1\}^n \), each bit-string \( K \in \{0,1\}^n \), each \( m \geq 1 \), and every vertex \( i \in \text{Input/Output} \) we define:

\[
\mu_m^{B,K,j}(e_i^{1-j}) = \begin{cases} 
    h_i^{1-j} & \text{if } B_i = 1, \\
    d_i^{1-j} & \text{if } B_i = 0.
\end{cases}
\]

For the input/output gadgets in circuit \( 1 - j \), the situation is the largely the same as for a \( \text{Not} \)-gate with depth \( d(C) + 1 \), and the edge chosen depends on \( F(B)_i \). However, one difference is that we do not define a best-response for the case where \( m = 1 \), because the input/output gadget does not reset until the second iteration, and our proof does not depend
on the best response chosen in iteration one. Formally, for each bit-string $B \in \{0, 1\}^n$, each bit-string $K \in \{0, 1\}^n$, each $m > 1$, and every vertex $i \in \text{INPUT/OUTPUT}$ we define:

$$
\mu^{B,K,j}_{m}(e^j_i) = \begin{cases} 
    h^j_i & \text{if } m > d(i) + 3 \text{ and } F(B)_i = 1, \\
    d^j_i & \text{otherwise}.
\end{cases}
$$

Finally, we define the best responses for the vertices $q^j$ as follows. For each bit-string $B \in \{0, 1\}^n$, each bit-string $K \in \{0, 1\}^n$, each $m$ in the range $1 \leq m \leq \text{Delay}(j,K) - 1$, and every vertex $i \in \text{INPUT/OUTPUT}$ we define:

$$
\mu^{B,K,j}_{m}(q^j_i,0) = \begin{cases} 
    e^j_i & \text{if } m = 1, \\
    q^j_i,1 & \text{if } m > 1.
\end{cases}
$$

$$
\mu^{B,K,j}_{m}(q^{1-j}_i,0) = \begin{cases} 
    e^{1-j}_i & \text{if } m = 1.
\end{cases}
$$

5. The Proof

In this section we give the proof for Lemma 4.2. Let $B, K \in \{0, 1\}^n$ be two bit-strings, let $j \in \{0, 1\}$, and let $m$ be in the range $1 \leq m \leq \text{Delay}(j,K) - 1$. We must show that greedy all-switches strategy improvement switches $\chi^{B,K,j}_{m} \to \chi^{B,K,j}_{m+1}$.

Let $\sigma$ be a strategy that agrees with $\chi^{B,K,j}_{m}$. Since we are using the all-switches switching rule, we can consider each vertex $v$ independently, and must show that the most appealing outgoing edge at $v$ is the one specified by $\chi^{B,K,j}_{m+1}$ (in our construction there will always be exactly one most appealing edge, so we do not care how ties are broken by the switching rule). Hence, the majority of the proof boils down to calculating the valuation of each outgoing edge of $v$, and then comparing these valuations.

To compare the valuation of two outgoing edges $(v, u)$ and $(v, w)$, we usually use the following technique. First we consider the two paths $\pi_1$ and $\pi_2$ that start at $u$ and $w$, respectively, and follow $\sigma$ and $\text{Br}(\sigma)$. Then we find the first vertex $v'$ that is contained in both paths. Since the $\sqsubseteq$ relation only cares about the maximum difference between the two paths, all priorities that are visited after $v'$ are irrelevant, since they appear in both $\text{Val}^\sigma(u)$ and $\text{Val}^\sigma(w)$. On the other hand, since each priority is assigned to at most one vertex, all of the priorities visited by $p_1$ before reaching $v'$ are contained in $\text{Val}^\sigma(u)$ and not contained in $\text{Val}^\sigma(w)$, and all of the priorities visited by $p_2$ before reaching $v'$ are contained in $\text{Val}^\sigma(w)$ and not contained in $\text{Val}^\sigma(u)$. So it suffices to find the largest priority on the prefixes of $p_1$ before $v'$ and the prefix of $p_2$ before $v'$. The parity of this priority then determines whether $\text{Val}^\sigma(u) \sqsubseteq \text{Val}^\sigma(w)$ according to the rules laid out in the definition of $\sqsubseteq$.

We now give an outline of the proof.

- The fact that the two clocks switch through their respective strategies follows from Lemma 4.1.
- The difference in valuation between the states $r^j$ and $s^j$ of the clock are the driving force of the construction. In Appendix A, we give two lemmas that formalize this difference.
- Next, in Appendix B, we prove that the best-response strategies defined in Section 4 are in fact the best responses. That is, we show that $\mu^{B,K,j}_{m}$ is a best response to every strategy $\sigma$ that agrees with $\chi^{B,K,j}_{m}$. 

In Appendix B.4, we give two key lemmas that describe the valuations of the output stats \(\sigma_i^j\). These lemmas show three important properties. Firstly, if \(m \leq d(i) + 2\), then the valuation of \(\sigma_i^j\) is low, so there is no incentive to switch to \(\sigma_i^j\) before gate \(i\) is evaluated. Secondly, if \(m > d(i) + 2\) and the gate evaluates to 0, then the valuation of \(\sigma_i^j\) remains low. Finally, if \(m > d(i) + 2\) and the gate evaluates to 1, then the valuation of \(\sigma_i^j\) is high. These final two properties allow the gates with depth strictly greater than \(i\) to compute their outputs correctly.

The rest of the proof consists of proving that all vertices switch to the correct outgoing edge. The states \(\sigma_i^j\) in the OR gate gadgets are dealt with in Appendix C. The states \(t_{i,j}^j\) in the NOT gates are dealt with in Appendix D. The states \(d_i^j\) in the NOT gates are dealt with in Appendix E. The states \(z^j\) and \(z^{1-j}\) are dealt with in Appendix F, and the states \(y^j\) and \(y^{1-j}\) are dealt with in Appendix G. The states \(p^j\) and \(p^{1-j}\) are dealt with in Appendix H and the states \(h_{i,0}^j\) are dealt with in Appendix I. Finally, the states in the INPUT/OUTPUT gates, which behave in a largely identical way to the NOT gates, are dealt with in Appendix J.

All of the above combines to provide a proof for Lemma 4.2.

Having shown this Lemma, we can now give the reduction from the problem BitSwitch to the problem EdgeSwitch. Given a circuit iteration instance \((F, B, z)\), we produce the parity game \(G\) corresponding to \(F\), we use \(\chi_{2,0}^{B,1.0}\) as the initial strategy, and if \(i \in \text{INPUT/OUTPUT}\) is the input/output gate corresponding to index \(z\), then we will monitor whether the edge from \(d_i^0\) to \(e_i^0\) is ever switched by greedy all-switches strategy improvement.

We therefore produce the instance \(\text{EdgeSwitch}(G, (d_i^0, e_i^0), \chi_{2,0}^{B,1.0})\). We must take care to ensure that \(\chi_{2,0}^{B,1.0}\) is a terminating strategy, which is proved in the following Lemma.

**Lemma 5.1.** We have that \(\chi_{2,0}^{B,1.0}\) is a terminating strategy.

**Proof.** Firstly, since we use the same strategies as Friedmann in the clock, we do not need to prove that theses portions of the strategies are terminating, because this has already been shown by Friedmann. In particular, this implies that all paths starting at \(s_i^j\) and \(r_i^j\) for \(j \in \{0, 1\}\) will eventually arrive at the sink \(x\). Therefore, it is sufficient to show that the first component of \(\text{Val}_{v_j}^{B,1.0}(v)\) is 1 for every vertex \(v\) in the circuits.

Observe that, in the strategy \(\chi_{2,0}^{B,1.0}\), we have that the only possible cycles that player Odd can form in the best response are two-vertex cycles of the form \(d_i^j\) and \(e_i^j\), but these cycles have an even priority, so the best response can not choose them. In particular, it is not possible to form a cycle that passes through the input/output gadgets in both circuits, because the path that starts at \(d_i^0\) for every input/output gate \(i\) must eventually arrive at \(s_i^j\). Thus, we have that all paths starting at all vertices in the circuits that follow \(\chi_{2,0}^{B,1.0}\) and its best response will eventually arrive at this sink \(x\).

Now all that remains is to argue that \(\text{EdgeSwitch}(G, (d_i^0, e_i^0), \chi_{2,0}^{B,1.0})\) is true if and only if \(\text{BitSwitch}(F, B, z)\) is true. To do this, we simply observe that the sequence of strategies used in Lemma 4.2 only ever specify that \(d_i^0\) must be switched to \(e_i^0\) in the case where there is some even \(j\) such that \(F^j(B) = 1\). At all other times, the vertex \(d_i^0\) chooses an edge other that \(e_i^0\). Hence, the reduction is correct, and we have shown Theorem 1.2.
6. Other Algorithms

Other strategy improvement algorithms. As we mentioned in the introduction, Theorem 1.2 implies several results about other algorithms. In particular, discounted games and simple-stochastic games both have natural strategy improvement algorithms given by Puri [36], and Condon [4], respectively. Friedmann showed that if you take a one-sink parity game, and apply the natural reduction from parity games to either discounted or simple stochastic games, then the greedy variants of Puri’s and Condon’s algorithms will switch exactly the same edges as the algorithm of Vöge and Jurdziński [15, Corollory 9.10 and Lemma 9.12]. Hence, Theorem 1.2 also implies the discounted and simple-stochastic cases of Corollary 1.3.

One case that was missed by Friedmann was mean-payoff games. There is a natural strategy improvement algorithm [14] for mean-payoff games that adopts the well-known gain-bias formulation from average-reward MDPs [37]. In this algorithm, the valuations has two components: the gain of a vertex gives the long-term average-reward that can be obtained from that vertex under the current strategy, and the bias measures the short term deviation from the long-term average.

We argue that, if we apply the standard reduction from parity games to mean-payoff games, and then set the reward of $x$ to 0, then the gain-bias algorithm for mean-payoff games switches exactly the same edges as the algorithm of Vöge and Jurdziński. The standard reduction from parity games to mean-payoff games [26,36] replaces each priority $p$ with the weight $(-m)^p$, where $m$ denotes the number of vertices in the parity game. By setting the weight of $x$ to 0, we ensure that the long-term average reward from each state is 0. Previous work has observed [12], that if the gain is 0 at every vertex, then the bias represents the total reward that can be obtained from each state. It is not difficult to prove that, after the standard reduction has been applied, the total reward that can be obtained from a vertex $v$ is larger than the total reward from a vertex $u$ if and only if $\text{Val}^\sigma(u) \sqsubseteq \text{Val}^\sigma(v)$ in the original parity game. This is because the rewards assigned by the standard reduction grow quickly enough so that only the largest priority visited matters. Hence, we also have the mean-payoff case of Corollary 1.3.

Björklund and Vorobyov have also devised a strategy improvement algorithm for mean-payoff games. Their algorithm involves adding an extra sink vertex, and then adding edges from every vertex of the maximizing player to the sink. Their valuations are also the total reward obtained before reaching the sink. We cannot show a similar result for their algorithm, but we can show a result for a variant of their algorithm that only gives additional edges to a subset of the vertices of the maximizing player. To do this, we do the same reduction as we did for the gain-bias algorithm, and then we only add an edge from $x$ to the new sink added the Björklund and Vorobyov. The same reasoning as above then implies that the Björklund-Vorobyov algorithm will make the same switches as the Vöge-Jurdziński algorithm.

Unique sink orientations. As mentioned in the introduction, there is a relationship between strategy improvement algorithms and sink-finding algorithms for unique sink orientations. Our result already implies a similar lower bound for sink-finding algorithms applied to unique sink orientations. However, since the vertices in our parity game have more than two outgoing edges, these results only hold for unique sink orientations of grids. The more commonly studied model is unique sink orientations of hypercubes, which correspond
to binary parity games, where each vertex has at most two outgoing edges. We argue that our construction can be formulated as a binary parity game.

Friedmann has already shown that his construction can be formulated as a binary parity game [15], so we already have that the clocks can be transformed so that they are binary. Furthermore, since our Not-gates and our Input/Output-gates are taken directly from Friedmann’s bit gadget, we can apply Friedmann’s reduction to make these binary. In particular, note that all of the extra states that we add to the input/output gate are binary, so these states do not need any modification.

The only remaining part of the construction is the Or-gate, which has four outgoing edges. We replace the existing gadget with a modified gadget, shown in Figure 12.

![Figure 12: The binary OR gate.](image)

| Vertex | Conditions | Edges | Priority | Player |
|--------|------------|-------|----------|--------|
| \( o_i^j \) | \( j \in \{0, 1\}, \ i \in \text{OR} \) | \( s_i^j, o_i^j \) | P(4, i, 0, j, 1) | Even |
| \( o_{i,1}^j \) | \( j \in \{0, 1\}, \ i \in \text{OR} \) | \( r_i^j, o_{i,2}^j \) | P(4, i, 1, j, 1) | Even |
| \( o_{i,2}^j \) | \( j \in \{0, 1\}, \ i \in \text{OR} \) | InputState(i, j, 1), InputState(i, j, 2) | P(4, i, 2, j, 1) | Even |

This gadget replaces the single vertex of the original Or-gate, with three binary vertices. The only significant difference that this gadget makes to the construction is that now it can take up to two strategy improvement iterations for the Or-gate to compute its output. This is because, we may have to wait for \( o_{i,2}^j \) to switch before \( o_{i,1}^j \) can switch. The vertex \( o_i^j \) always chooses the edge \( o_{i,1}^j \) during the computation, because the valuation of \( r_i^j \) is larger than the valuation of \( s_i^j \).

To deal with this, we can redesign the construction so that each Not-gate \( i \) is computed on iteration \( 2i \) rather than iteration \( i \), and each Or-gate is computed before iteration \( 2i \). This involved making the following changes:
THE COMPLEXITY OF ALL-SWITCHES STRATEGY IMPROVEMENT

- The length of the deceleration lane in the two clocks must be extended by $2k$, to account for the $2k$ extra iterations it takes for the circuits to compute ($k$ extra iterations for circuit 0 and $k$ extra iterations for circuit 1). Moreover, the delays for both of the clocks must be increased by $k$.
- For the same reason, the length of the modified deceleration lanes in the NOT and INPUT/OUTPUT gates must be increased by $2k$.
- Finally, the edge to $o^2_{\text{InputState}(i,j)}$ must be moved from $t_{i,d(i)}$ to $t_{i,2d(i)}$.

Once these changes have been made, we have produced a binary parity game.

One final thing we must be aware of is that we only get a unique-sink orientation if there is never a tie between the valuation of two vertices. This, however, always holds in a one-sink game where every vertex has a distinct priority, because all paths necessarily contain a distinct set of priorities, which prevents ties in the $\sqsubseteq$ ordering. Therefore, we have the $\text{PSPACE}$-completeness result for the BOTTOMANTIPODAL algorithm claimed in Corollary 1.7.

7. THE OPTIMAL STRATEGY RESULT

We are also able to prove a result about the complexity of determining which optimal strategy is found by the Vöge-Jurdziński algorithm. However, we cannot formulate this in the context of a one-sink game, because any result of this nature must exploit *ties in valuations*. In a one-sink game, since every vertex has a different priority, no two paths can have the same set of priorities, so ties are not possible. Hence, for a one-sink game, there will be a unique optimal strategy, and so the complexity of finding it can be no harder than solving the parity game itself, and this problem is not $\text{PSPACE}$-complete unless $\text{PSPACE} = \text{UP} \cap \text{coUP}$.

On the other hand, ties in valuations are possible in the original Vöge-Jurdziński algorithm. This is because the first component of their valuation is not necessarily 1, and so the second component does not necessarily contain every priority along the relevant path (recall that priorities smaller than the first component are not included in the second component). These facts mean that it is possible to construct parity games that have multiple optimal strategies under the Vöge-Jurdziński valuation.

**Our modified construction.** We will use a slight modification of our construction to show that computing the optimal strategy found by the Vöge-Jurdziński algorithm is $\text{PSPACE}$-complete. The key difference is the addition of a *third* clock with $n + 1$ bits, which will be indexed by 2. We remove a single edge from this clock: the edge from $e^2_{n+1}$ to $h^2_{n+1}$ is removed.

Recall that in the clock construction, the odd vertices $e^j_i$ do not use the edge to $h^j_i$ unless they are forced to by the vertex $d^j_i$ selecting the edge to $e^j_i$. Hence, until the $n + 1$th bit is flipped, the third clock behaves like any other clock. When the $n + 1$th bit is flipped, after $2^n$ iterations have taken place, a new cycle is formed with a very large even priority.

We also modify the edges that leave $d^1_z$. For each edge $e = (d^1_z, u)$ we do the following:

1. We delete $e$.
2. We introduce a new vertex $v_u$ owned by player Even. This vertex is assigned an insignificant priority that, in particular, is much smaller than the priorities assigned to $e^2_{n+1}$ and $d^2_{n+1}$.
3. We add the edges $(d^1_z, v_u)$, $(v_u, u)$, and $(v_u, f^2_{n+1})$. 
The following table summarises the extra clock that we add to the construction, and the new outgoing edges from $d^1_z$. For ease of notation, we define $U = \{y^1, z^1, e^1_z\} \cup \{a^1_{z,l} : 1 \leq l \leq 2k + 4n + 6\}$ to be the original outgoing edges from $d^1_z$ that will now be replaced. Moreover, we assume that each vertex $u$ is represented by a number in the range $1 \leq u \leq |U|$, which will be used as part of the priority for $v_u$.

| Vertex | Conditions | Edges | Priority                  | Player |
|--------|------------|-------|---------------------------|--------|
| $t^0_l$ | $1 \leq l \leq 2k + 4n + 6$ | $r^l, s^l$ | $P(2, 0, 2k + 4n + 4, 2, 0)$ | Even   |
| $t^1_l$ | $1 \leq l \leq 2k + 4n + 6$ | $r^l, s^l, t^l_{l-1}$ | $P(2, 0, l, 2, 1)$ | Even   |
| $d^1_i$ | $1 \leq i \leq n$ | $e^i_i, s^i_i, r^i_i$ | $P(1, i, 0, 2, 1)$ | Even   |
| $a^1_i$ | $1 \leq i \leq n$ | $a^i_i$ for $1 \leq l \leq 2k + 2n + 6 + 2i$ | $P(1, i, 1, 2, 0)$ | Odd   |
| $i^1_i$ | $1 \leq i \leq n$ | $d^i_i$ | $P(1, i, 1, 2, 0)$ | Even   |
| $f^1_i$ | $1 \leq i \leq n$ | $x, g^i_i$ for $i < l \leq n$ | $P(8, i, 0, 2, 1)$ | Even   |
| $h^1_i$ | $1 \leq i \leq n$ | $k^i_i$ | $P(8, i, 2, 2, 0)$ | Even   |
| $x^2_r$ | $1 \leq i \leq n$ | $x, f^2_r$ for $1 \leq l \leq n$ | $P(7, 0, 0, 2, 0)$ | Even   |
| $f^2_r$ | $1 \leq i \leq n$ | $x, g^2_r$ for $1 \leq l \leq n$ | $P(7, 0, 1, 2, 0)$ | Even   |
| $v_u$ | $u \in U$ | $u$ | $P(0, 0, 0, u, 0)$ | Even   |
| $d^1_z$ | $v_u$ | $v_u$ for all $u \in U$ | $P(4, i, 0, j, 1)$ | Even   |

**PSPACE-completeness.** We now argue how this modified construction provides a PSPACE-hardness proof for the optimal strategy decision problem. Before the $n$th bit of the third clock flips, the edge $(v_u, f^2_{n+1})$ is never switchable due to the large odd priority assigned to $f^2_{n+1}$, so this modification does not affect the computation of $F^{2^n}(B)$. On the other hand, once the $n$th bit of the third clock flips, all edges of the form $(v_u, f^2_{n+1})$ immediately become switchable, because the first component of the valuation of $f^2_{n+1}$ is now a large even priority, and not 1. So all of these edges will be switched simultaneously.

The key thing to note is that, since the priorities assigned to the vertices $v_u$ are insignificant, they do not appear in the second component of the valuation, and so vertex $d^1_z$ is now indifferent between all of its outgoing edges. Moreover, the vertices $v_u$ never switch away from $f^2_{n+1}$ for the following reasons:

- The only even cycle that can be forced by player Even is the one that uses $d^2_{n+1}$ and $e^2_{n+1}$. So, these vertices must select a strategy that reaches this cycle eventually.
- All priorities used in the circuits are smaller than the priority of the cycle between $d^2_{n+1}$ and $e^2_{n+1}$. So, the second component of the valuation function is irrelevant, and the only way of improving the strategy would be to find a shorter path to the cycle.
- The vertices $v_u$ are the only vertices that have edges to the third clock, so the only way a vertex $v_u$ could reach the third clock would be to travel through both circuits to reach $d^1_z$, and then use a different vertex $v_u'$, but this would be a much longer path, and therefore this would have a lower valuation.

Hence, the vertices $v_u$ will never switch away from $f^2_{n+1}$.

Observe that, after $2^n$ iterations, the input/output gadgets in circuit $1 - j$ store the value of $F^{2^n}(B)$, and therefore $d^1_1$ chooses the edge to $e^1_z$ if and only if the $z$th bit of $F^{2^n}(B)$ is 1. The above argument implies that $d^1_1$ does not switch again, so in the optimal strategy found by the algorithm, the vertex $d^1_z$ chooses the edge to $e^1_z$ if and only if the $z$th bit of $F^{2^n}(B)$
is 1. Thus, we have that computing the optimal strategy found by the Vöge-Jurdziński strategy improvement algorithm is \textsc{PSPACE}-complete, as claimed in Theorem 1.5.

**Other games.** We also get similar results for the gain-bias algorithm for mean-payoff games, and the standard strategy improvement algorithms for discounted and simple stochastic games. For the most part, we can still rely on the proof of Friedmann for these results. This is because, although we do not have a one-sink game, the game behaves as a one-sink game until the \( n + 1 \)th bit in the third clock is flipped. An easy way to see this is to reinstate the edge between \( e_{n+1}^2 \) and \( h_{n+1}^2 \) to create a one-sink game, and observe that, since the edge is not used in the best response until the \( n + 1 \)th bit is flipped, it cannot affect the sequence of strategies visited by strategy improvement. Once the \( n + 1 \)th bit has flipped, we only care about making \( d_1^z \) indifferent between its outgoing edges, and in this section we explain how this is achieved.

For mean-payoff games, we use the same reduction as we did in Section 6 to our altered construction. After doing this, we set the weight of the vertices \( v_u \) to 0 to ensure that \( d_1^z \) will be exactly indifferent between all of its outgoing edges once these vertices switch to \( f_{n+1}^2 \). This gives the result for the gain-bias algorithm in mean-payoff games.

For discounted games, once the standard reduction from mean-payoff to discounted games has been applied, the proof of Friedmann already implies that the discounted game algorithm makes the same decisions as the Vöge-Jurdziński algorithm for the vertices other than \( d_1^z \). The only worry is that the discount factor may make the vertex \( d_1^z \) not indifferent between some of its outgoing edges. However, it is enough to note that all paths from \( d_1^z \) to \( f_{n+1}^2 \) have length 2, and therefore the vertex will be indifferent no matter what discount factor is chosen. This gives the result for the standard strategy improvement algorithm for discounted games.

Finally, after applying the standard reduction from discounted to simple-stochastic games, the proof of Friedmann can be applied to argue that the valuations in the simple stochastic game are related to the valuations in the discounted game by a linear transformation. Hence, \( d_1^z \) will still be indifferent between its outgoing edges after the \( n + 1 \)th bit is flipped. This gives the result for the standard strategy improvement algorithm for simple stochastic games. Thus, we have the claimed results from Corollary 1.6.

### 8. Open problems

Strategy improvement generalizes policy iteration which solves mean-payoff and discounted-payoff Markov decision processes [37]. The exponential lower bounds for greedy all-switches have been extended to MDPs. Fearnley showed that the second player in Friedmann’s construction [15] can be simulated by a probabilistic action, and used this to show an exponential lower bound for the all-switches variant of policy iteration of average-reward MDPs [8]. This technique cannot be applied to the construction in this paper, because we use additional Odd player states (in particular the vertices \( q_{1,1}^j \)) that cannot be translated in this way. Can our \textsc{PSPACE}-hardness results be extended to all-switches strategy improvement for MDPs?

Also, there are other pivoting algorithms for parity games that deserve attention. It has been shown that Lemke’s algorithm and the Cottle-Dantzig algorithm for the P-matrix linear complementarity problem (LCP) can be applied to parity, mean-payoff, and discounted games [11, 29]. It would be interesting to come up with similar \textsc{PSPACE}-completeness results
for these algorithms, which would also then apply to the more general P-matrix LCP problem.
THE COMPLEXITY OF ALL-SWITCHES STRATEGY IMPROVEMENT

Appendix A. Facts about the clock

In this section we prove two important lemmas about the clocks. The first lemma shows an important property about the difference in valuation between \( r^j \) and \( s^j \) for the clock used by circuit \( j \). The second lemma considers the difference in valuation across the two clocks, by comparing the valuations of \( r^j, s^j, r^{1-j} \), and \( s^{1-j} \).

**Lemma A.1.** Let \( \sigma \) be a strategy that agrees with \( \chi^K_m \) for some \( m \) in the range \( 1 \leq m \leq \text{Length}(K) \), some clock-value \( K \in \{0,1\}^n \), and some \( j \in \{0,1\} \). We have:

1. If \( m = \text{Length}(K) - 1 \) then \( \text{Val}^\sigma(r^j) \sqsubseteq \text{Val}^\sigma(s^j) \).
2. If \( m < \text{Length}(K) - 1 \) then \( \text{Val}^\sigma(s^j) \sqsubseteq \text{Val}^\sigma(r^j) \).

In both cases, we have that \( \text{MaxDiff}^\sigma(s^j, r^j) \geq P(7,0,0,0) \).

**Proof.** We begin with the first case. In this case, by definition, we have that the path that starts at \( s^j \) and follows \( \sigma \) moves to \( f^j_i \) for some \( i \), whereas the path that starts at \( r^j \) and follows \( \sigma \) moves to \( g^j_i \) for some \( i' \neq i \). There are two possibilities.

1. If \( i > i' \), then since \( i \) is the least significant zero in \( K \), we must have that \( i' = \text{NextBit}(K,0) = 1 \). Hence, the path that starts at \( g^j_i \) passes through the bit gadgets for all bits strictly smaller than \( i \) before eventually arriving at \( g^j_{\text{NextBit}(K,i)} \) (or \( x \) if \( \text{NextBit}(K,i) \) is not defined). In particular, since the path does not pass through \( h^j_1 \) the largest priority on the path is strictly smaller than \( P(8,i,2,j,0) \).

   On the other hand, the path that starts at \( f^j_i \) eventually arrives at \( g^j_{\text{NextBit}(K,i)} \) (or \( x \) if \( \text{NextBit}(K,i) \) is not defined) and it does pass through \( h^j_1 \). The largest priority on this path is \( P(8,i',2,j,0) \), and since the priority is even, we can conclude that \( \text{Val}^\sigma(r^j) \sqsubseteq \text{Val}^\sigma(s^j) \).

2. If \( i < i' \), then since \( i' \) is the least significant one in \( K \), we must have that \( i = 1 \). Hence, the path that starts at \( f^j_i \) eventually moves to \( k^j_1 \) and then directly to \( g^j_1 \). The largest priority on this path is \( P(8,i',2,j,0) \), and since this is even, we can conclude that \( \text{Val}^\sigma(r^j) \sqsubseteq \text{Val}^\sigma(s^j) \).

We now move on to the second case. In this case, by definition, we have that the path that starts at \( s^j \) moves to \( f^j_i \) for some \( i \), whereas the path that starts at \( r^j \) moves to \( g^j_i \) and then to \( f^j_i \). Since the priority on \( g^j_i \) is strictly smaller than \( P(7,0,1,j,0) \), we have that \( \text{MaxDiff}^\sigma(r^j,s^j) = P(7,0,1,j,0), \) which the priority assigned to \( r^j \). Since this priority is even, we have that \( \text{Val}^\sigma(s^j) \sqsubseteq \text{Val}^\sigma(r^j) \), as required.

Observe that in all cases considered above, we have shown that \( \text{MaxDiff}^\sigma(r^j,s^j) \geq P(7,0,0,0,0) \) as required. Hence, we have completed the proof of this lemma.

**Lemma A.2.** Let \( \sigma \) be a strategy that agrees with \( \chi_{m,K,j}^{B,K} \) for some \( m \geq 1 \), some bit-strings \( B,K \in \{0,1\}^n \), and some \( j \in \{0,1\} \). We have:

1. If \( m = \text{Delay}(j,K) - 1 \), then \( \text{Val}^\sigma(r^{1-j}) \sqsubseteq \text{Val}^\sigma(r^j) \sqsubseteq \text{Val}^\sigma(s^{1-j}) \) and
   \[ \text{MaxDiff}^\sigma(r^{1-j},s^j) \geq P(7,0,0,0,0) \]
   and \( \text{MaxDiff}^\sigma(r^{1-j},r^j) \geq P(7,0,0,0,0) \).

2. If \( m < \text{Delay}(j,K) - 1 \), then \( \text{Val}^\sigma(r^{1-j}) \sqsubseteq \text{Val}^\sigma(s^j) \sqsubseteq \text{Val}^\sigma(r^j) \) and
   \[ \text{MaxDiff}^\sigma(r^{1-j},s^j) \geq P(7,0,0,0,0) \]
   and \( \text{MaxDiff}^\sigma(s^j,r^{1-j}) \geq P(7,0,0,0,0) \).
Proof. We begin with the second claim. The fact that $\text{Val}^\sigma(s^j) \subseteq \text{Val}^\sigma(r^j)$ follows from part 2 of Lemma A.1, so it is sufficient to show that $\text{Val}^\sigma(r^{1-j}) \subseteq \text{Val}^\sigma(s^j)$. There are two cases to consider, based on whether $j = 0$ or $j = 1$.

(1) If $j = 0$, then clock $j$ uses bit-string $K$, and clock $1-j$ uses bit-string $K-1$. Observe that the clock strategies specify that the path starting at $s^j$ visits $h_i^j$ if and only if $K_i = 1$. Similarly, the path starting at $r^{1-j}$ visits $h_i^{1-j}$ if and only if $(K-1)_i = 1$. If $i'$ is the index of the least significant 1 in $K$, then we have that the path that starts at $s^j$ visits $h_i^{1-j}$ and $k_i^j$, and the path that starts at $s^{1-j}$ does not visit these vertices. Moreover, these two paths are the same after this point. Hence, we have that $\text{MaxDiff}(s^j, r^{1-j})$ is $P(8, i', 2, j, 0)$, and since this priority is even, we can conclude that $\text{Val}^\sigma(r^{1-j}) \subseteq \text{Val}^\sigma(s^j)$.

(2) If $j = 1$, then both clocks use bit-string $K$. Hence, the paths starting at $s^j$ and $r^{1-j}$ use the same path through their respective clocks. So, if $i'$ is the index of the most significant 1 in $K$, then we have that $P(8, i', 2, 0, 0)$ is the largest priority on the path starting at $r^{1-j} = s^0$, and $P(8, i', 2, 1, 0)$ is the largest priority on the path starting at $s^1 = s^1$. Thus, $\text{MaxDiff}(s^j, r^{1-j}) = P(8, i', 2, 1, 0)$, and since this priority is even and contained in $\text{Val}^\sigma(s^j)$ we can conclude that $\text{Val}^\sigma(r^{1-j}) \subseteq \text{Val}^\sigma(s^j)$.

We now move on to the first claim. Here the same reasoning as we gave for the second case can be used to prove that $\text{Val}^\sigma(r^{1-j}) \subseteq \text{Val}^\sigma(s^j)$, and therefore Lemma A.1 implies that $\text{Val}^\sigma(r^{1-j}) \subseteq \text{Val}^\sigma(r^j)$. What remains is to prove that $\text{Val}^\sigma(r^j) \subseteq \text{Val}^\sigma(s^{1-j})$. Again there are two cases to consider.

(1) If $j = 0$, then clock $j$ uses bit-string $K$, and clock $1-j$ is about to transition from bit-string $K-1$ to bit-string $K$. In fact, the path from $s^{1-j}$ is already the path for bit-string $K$, so the proof from item 2 above can be reused.

(2) If $j = 1$, then clock $j$ uses bit-string $K$, and clock $1-j$ is about to transition from bit-string $K$ to bit-string $K+1$. In fact, the path from $s^{1-j}$ is already the path for bit-string $K+1$, so the proof from item 1 above can be reused.

Finally, we observe that all of the maximum difference priorities used in the proof are strictly larger than $P(7, 0, 0, 0, 0)$, which completes the proof. □

Appendix B. Best responses

In this section, we prove that the best responses defined in Section 4 are indeed best responses to $\chi_{m,B,K,j}$. There are two types of odd vertices used in the construction: the vertices $e_i^j$ used in the NOT and Input/Output gates, and the vertices $q_{i,0}^j$ used in the Input/Output gates. We begin by proving a general lemma concerning the vertices $e_i^j$ used in the NOT and Input/Output gates.

Lemma B.1. Let $\sigma$ be a strategy that agrees with $\chi_{m,B,K,j}$ for some bit-strings $B, K \in \{0,1\}^n$, some $m$ in the range $1 \leq m \leq \text{Delay}(j, K) - 1$, and some $j \in \{0,1\}$. For every $i \in \text{NOT} \cup \text{Input/Output}$, and every $l \in \{0,1\}$, we have that if $\sigma(d_i^l) = e_i^l$, then $\text{Br}(\sigma)(e_i^l) \neq d_i^l$.

Proof. Note that if player Odd uses the edge from $e_i^l$ to $d_i^l$, then this would create a cycle with largest priority $P(1, i, 1, j, 0)$, which is even. Since the game is a one-sink game, and since the initial strategy is terminating, we have that Odd can eventually reach the odd cycle at $x^j$ from the vertices $r^j, r^{1-j}, s^j, s^{1-j}$. Furthermore, Odd can reach one of these four
vertices by moving to \( h_i^1 \). Since the odd cycle at \( x^j \) has priority smaller than \( P(1,i,1,j,0) \), we can conclude that \( \text{Br}(\sigma)(e_i^j) \neq d_i^1 \).

We now proceed to prove individual lemma for each of the vertices that belong to player Odd. Each type of Odd vertex will be considered in a different subsection.

B.1. The vertices \( q_{i,0}^j \). We now consider the vertices \( q_{i,0}^j \) for \( i \in \text{INPUT/OUTPUT} \). The first lemma considers the case where \( l = j \), and the second lemma considers the case where \( l = 1 - j \).

**Lemma B.2.** Let \( \sigma \) be a strategy that agrees with \( \chi_m^{B,K,j} \) for some bit-strings \( B,K \in \{0,1\}^n \), some \( m \) in the range \( 1 \leq m \leq \text{Delay}(j,K) - 1 \), and some \( j \in \{0,1\} \). For every \( i \in \text{INPUT/OUTPUT} \), we have that \( \text{Br}(\sigma)(q_{i,0}^j) = \mu_m^{B,K,j}(q_{i,0}^j) \).

**Proof.** There are two cases to consider.

- **If** \( m = 1 \), then \( \text{then we must show that the edge to } e_i^j \text{ is chosen by Odd in the best response. Consider a strategy } \tau \text{ where } \tau(e_i^j) = h_i^1, \text{ and } \tau(q_{i,0}^j) = e_i^j \). When \( \tau \) is played against \( \sigma \), the path that starts at \( e_i^j \) eventually arrives at \( r^{1-j} \), and the largest priority on this path is strictly smaller than \( P(6,d(C) + 2,0,j,0) \). On the other hand, taking the edge to \( q_{i,1}^j \) leads directly to \( r^{1-j} \) while visiting the priority \( P(6,d(C) + 2,0,j,0) \). Since this priority is even, we can conclude that Odd would prefer to play \( \tau \) than to use the edge from \( q_{i,0}^j \) to \( q_{i,1}^j \) in his best response. Therefore, we must have that \( \text{Br}(\sigma)(q_{i,0}^j) = e_i^j \), as required.

- **If** \( m > 1 \), then we must show that the edge to \( q_{i,1}^j \) is the least appealing edge at \( q_{i,0}^j \).

Observe that the path that starts at \( e_i^j \) and follows \( \sigma \) eventually arrives at \( r^j \), and every priority on this path that is strictly smaller than \( P(7,0,0,0,0) \). On the other hand, the path that starts at \( q_{i,1}^j \) moves directly to \( r^{1-j} \). Hence, we can apply Lemma A.2 (both parts) to argue that \( \text{Val}^\sigma(q_{i,1}^j) \supseteq \text{Val}^\sigma(e_i^j) \), as required.

**Lemma B.3.** Let \( \sigma \) be a strategy that agrees with \( \chi_m^{B,K,j} \) for some bit-strings \( B,K \in \{0,1\}^n \), some \( m \) in the range \( 1 \leq m \leq \text{Delay}(j,K) - 1 \), and some \( j \in \{0,1\} \). For every \( i \in \text{INPUT/OUTPUT} \), we have that \( \text{Br}(\sigma)(q_{i,0}^{1-j}) = \mu_m^{B,K,j}(q_{i,0}^{1-j}) \).

**Proof.** We must show that the edge to \( e_i^{1-j} \) is the least appealing edge at \( q_{i,0}^{1-j} \). Observe that the path that starts at \( e_i^{1-j} \) and follows \( \sigma \) will eventually arrive at either \( r^j \) or \( r^{1-j} \). In either case, the largest priority on this path will be strictly smaller than \( P(6,d(C) + 2,0,j,0) \). On the other hand, the path that starts at \( q_{i,1}^{1-j} \) moves directly to \( r^j \), and the largest priority on this path is \( P(6,d(C) + 2,0,j,0) \). Since this priority is even, we can conclude that \( \text{Val}^\sigma(e_i^{1-j}) \supseteq \text{Val}^\sigma(q_{i,0}^{1-j}) \), as required.

B.2. The vertices \( e_i^l \) in Not gates. The following lemma considers the vertices \( e_i^l \) for \( l = j \) and \( i \in \text{NOT} \). We do not need to prove a lemma for the case where \( l = 1 - j \) and \( i \in \text{NOT} \), because these vertices are in the non-computing circuit, and we do not specify strategies for the Not and Or gadgets in the non-computing circuits.
Lemma B.4. Let $\sigma$ be a strategy that agrees with $\chi_{m}^{B,K,j}$ for some bit-strings $B, K \in \{0,1\}^{n}$, some $m$ in the range $1 \leq m \leq \text{Delay}(j, K) - 1$, and some $j \in \{0,1\}$. For every $i \in \text{NOT}$, we have that $\text{Br}(\sigma)(e^{j}_{i}) = \mu_{m}^{B,K,j}(e^{j}_{i})$.

Proof. There are three cases to consider.

(1) If $m = 1$ then, the path that starts at $d^{j}_{i}$ and follows $\sigma$ moves directly to $e^{j}_{i}$. On the other hand, the path that starts at $h^{j}_{i}$ moves directly to $r^{j}$. All of the priorities on these paths are strictly smaller than $\text{P}(7,0,0,0,0)$, so we can apply Lemma A.1 part 2 to argue that $\text{Val}^{\sigma}(d^{j}_{i}) \subset \text{Val}^{\sigma}(d^{j}_{i})$, so therefore we have $\text{Br}(\sigma)(e^{j}_{i}) = d^{j}_{i}$.

(2) If $m > 1$ and either $m \leq d(i) + 2$, or $m > d(i) + 2$ and $\text{Eval}(B, I(i)) = 1$, then observe that the path that starts at $d^{j}_{i}$ and follows $\sigma$ eventually arrives at $r^{j}$, and that the largest priority on this path is strictly smaller than $\text{P}(6, i, 1, j, 0)$. On the other hand, the path that starts at $h^{j}_{i}$ and follows $\sigma$ moved directly to $r^{j}$, and the largest priority on this path is $\text{P}(6, i, 1, j, 0)$. Since this priority is even, we can conclude that $\text{Val}^{\sigma}(d^{j}_{i}) \subset \text{Val}^{\sigma}(e^{j}_{i})$, so therefore we have $\text{Br}(\sigma)(e^{j}_{i}) = d^{j}_{i}$.

(3) If $m > d(i) + 2$ and $\text{Eval}(B, I(i)) = 0$, then we have $\sigma(d^{j}_{i}) = e^{j}_{i}$, so we can apply Lemma B.1 to prove that $\text{Br}(\sigma)(e^{j}_{i}) = h^{j}_{i}$. 

B.3. The vertices $e^{j}_{i}$ in Input/Output gates. The following lemmas consider the vertices $e^{j}_{i}$ when $i \in \text{INPUT/OUTPUT}$. The first lemma considers the case where $l = j$, and the second lemma considers the case where $l = 1 - j$.

Lemma B.5. Let $\sigma$ be a strategy that agrees with $\chi_{m}^{B,K,j}$ for some bit-strings $B, K \in \{0,1\}^{n}$, some $m$ in the range $1 \leq m \leq \text{Delay}(j, K) - 1$, and some $j \in \{0,1\}$. For every $i \in \text{INPUT/OUTPUT}$, we have that $\text{Br}(\sigma)(e^{j}_{i}) = \mu_{m}^{B,K,j}(e^{j}_{i})$.

Proof. There are a number of cases to consider.

(1) If $m > 1$ and $F^{2}(B)_{i} = 0$ and either $m \leq d(i) + 3$, or $m > d(i) + 3$ and $F^{2}(B)_{i} = 0$, then the path that starts at $d^{j}_{i}$ eventually arrives at $r^{j}$, and the largest priority on this path is strictly smaller than $\text{P}(6, d(C) + 1, 1, j, 0)$. On the other hand, the path that starts at $h^{j}_{i,0}$ and follows $\sigma$ passes through $h^{j}_{i,1}$ and then arrives at $r^{j}$. The largest priority on this path is $\text{P}(6, d(C) + 1, 1, j, 0)$, and since this priority is even, we can conclude that $\text{Val}^{\sigma}(d^{j}_{i}) \subset \text{Val}^{\sigma}(h^{j}_{i,0})$. Therefore, we have that $\text{Br}(\sigma)(e^{j}_{i}) = d^{j}_{i}$.

(2) If $m > 1$ and $m > d(i) + 3$ and $F^{2}(B)_{i} = 1$, then $\sigma(d^{j}_{i}) = e^{j}_{i}$, and so we can apply Lemma B.1 to argue that $\text{Br}(\sigma)(e^{j}_{i}) = h^{j}_{i,0}$.

Lemma B.6. Let $\sigma$ be a strategy that agrees with $\chi_{m}^{B,K,j}$ for some bit-strings $B, K \in \{0,1\}^{n}$, some $m$ in the range $1 \leq m \leq \text{Delay}(j, K) - 1$, and some $j \in \{0,1\}$. For every $i \in \text{INPUT/OUTPUT}$, we have that $\text{Br}(\sigma)(e^{1-j}_{i}) = \mu_{m}^{B,K,j}(e^{1-j}_{i})$.

Proof. There are a number of cases to consider.

(1) If $m = 1$ and $B_{i} = 0$, then the path that starts at $d^{1-j}_{i}$ and follows $\sigma$ will eventually reach $r^{1-j}$, and the largest priority on this path is strictly smaller than $\text{P}(6, d(C) + 1, 1, j, 0)$. On the other hand, the path that starts at $h^{1-j}_{i,0}$ moves to $h^{1-j}_{i,1}$ and then arrives at $r^{1-j}$, and the largest priority on this path is $\text{P}(6, d(C) + 1, 1, j, 0)$. Since this priority is even, we have that $\text{Val}^{\sigma}(d^{1-j}_{i}) \subset \text{Val}^{\sigma}(h^{1-j}_{i,0})$ and therefore $\text{Br}(\sigma)(e^{1-j}_{i}) = d^{1-j}_{i}$. 

(2) $m > 1$ and $B_i = 0$, then the path that starts at $d_i^{1-j}$ moves to $r^j$, and the largest priority on this path is strictly smaller than $P(6, 0, 1, j, 0)$. On the other hand, the path that starts at $h_{i,0}^{1-j}$ moves to $h_{i,2}^{1-j}$ and then arrives at $r^j$, and the largest priority on this path is $P(6, 0, 1, j, 0)$. Since this priority is even, we have that $\text{Val}^o(d_i^{1-j}) \sqsubset \text{Val}^o(h_{i,0}^{1-j})$ and therefore $\text{Br}(\sigma)(e_i^{1-j}) = d_i^{1-j}$.

(3) If $B_i = 1$, then we have $\sigma(d_i^{1-j}) = e_i^{1-j}$, and we can apply Lemma B.1 to argue that $\text{Br}(\sigma)(e_i^{1-j}) = h_{i,0}^{1-j}$.

B.4. Gate outputs. In this section we give two key lemmas that describe the valuation of the output states $o_i^j$. The first lemma considers the case where $m = 1$ or $m = 2$, and the second lemma considers the case where $m \geq 3$.

**Lemma B.7.** Let $\sigma$ be a strategy that agrees with $\chi_m^{B,K,j}$ for some $K, B \in \{0, 1\}^n$, some $j \in \{0, 1\}^n$, and for $m = 1$ or $m = 2$. For every gate $i$, we have $\text{Val}^o(o_i^1) \sqsubset \text{Val}^o(r^j)$.

**Proof.** There are four cases to consider

(1) We begin by showing the claim for an input/output gate $i$ from circuit $1 - j$ in the case where $m = 1$. Note that Lemma B.6 implies that $\text{Br}(\sigma)(e_i^{1-j}) = d_i^{1-j}$. Observe that by definition, the path that starts at $d_i^j$ and follows $\sigma$ will trace a path through the gadgets for circuit $1 - j$, and will eventually reach $r^{1-j}$. Furthermore, the largest priority possible that can be seen along this path is $P(6, d(C) + 1, 1, j, 0) < P(7, 0, 0, 0, 0)$. Hence, we can apply Lemma A.2 to argue that $\text{Val}^o(o_i^1) \sqsubset \text{Val}^o(r^j)$.

(2) Now we consider an input/output gate $i$ from circuit $1 - j$ in the case where $m = 2$. Again, Lemma B.6 implies that $\text{Br}(\sigma)(e_i^{1-j}) = d_i^{1-j}$, but in this case since $m = 2$, we have that the vertices $y_i^{1-j}$ and $p_i^{1-j}$ have both switched to $r^j$. Hence, the path that starts at $o_i^{1-j}$ will eventually arrive at $r^j$. It can be verified that, whatever path is taken from $o_i^{1-j}$ to $r^j$, the largest priority along this path is $P(6, i, 0, j, 1)$ on the vertex $o_i^{1-j}$. Since this priority is odd, we have that $\text{Val}^o(o_i^1) \sqsubset \text{Val}^o(r^j)$.

(3) Next we consider the case where $i$ is a OR-gate. If $m = 1$ then we have that $\sigma(o_i^1) = s^j$, and if $m = 2$ then $\sigma(o_i^1) = r^j$. In both cases, we can use Lemma A.1 and the fact that the priority assigned to $o_i^1$ is odd, to conclude that $\text{Val}^o(o_i^1) \sqsubset \text{Val}^o(r^j)$.

(4) Finally, we consider the case where $i$ is a NOT-gate. We can apply Lemma B.4 to argue that $\text{Br}(\sigma)(e_i^j) = d_i^j$. If $m = 1$ then we have that $\sigma(d_i^j) = s^j$, and if $m = 2$ then $\sigma(d_i^j) = r^j$. In both cases, the highest priority on the path from $o_i^j$ to either $s^j$ or $r^j$ is the odd priority from $o_i^j$, so we can use this fact, along with Lemma A.1 to conclude that $\text{Val}^o(o_i^j) \sqsubset \text{Val}^o(r^j)$.

**Lemma B.8.** Let $\sigma$ be a strategy that agrees with $\chi_m^{B,K,j}$ for some $K, B \in \{0, 1\}^n$, some $j \in \{0, 1\}^n$, and some $m$ in the range $3 \leq m \leq \text{Delay}(j, K)$. For every gate $i$, we have:

1. If $m \leq d(i) + 2$, then $\text{Val}^o(o_i^1) \sqsubset \text{Val}^o(r^j).
2. If $m > d(i) + 2$ and $\text{Eval}(B, i) = 0$, then $\text{Val}^o(o_i^1) \sqsubset \text{Val}^o(r^j).
3. If $m > d(i) + 2$ and $\text{Eval}(B, i) = 1$, then $\text{Val}^o(r^j) \sqsubset \text{Val}^o(o_i^1)$ and:

$$P(6, 0, 0, 0, 0) \leq \text{MaxDiff}^\sigma(r^j, o_i^1) \leq P(6, i, 1, j, 0).$$
We will prove this claim by induction over the depth of the gates. For the base case we consider an input/output gate $i$ from circuit $1 - j$, which provide the input values for circuit $j$. Since we consider these gates to have depth 0, we always have $m > d(i) + 2$, so there are two cases to prove based on whether $B_i$ is zero or one. First, observe that since $m \geq 3$, the circuit mover gadgets attached to the input/output gadget for bit $i$ in circuit $1 - j$ have $\sigma(y^{1,j}) = r^j$. Since Delay$(1 - j, K) \geq d(C) + 3$, the definition given in (4.5) implies that the strategy at $d_i^{1,j}$ is determined by $B_i$. So we have the following two cases.

- If $B_i = 0$, then $\sigma(d_i^{1,j}) = a_i^{1,j}$ for some $l$. By definition, in the strategy $\sigma$, all paths from $a_i^{1,j}$ eventually arrive at $r^j$, and the maximum priority on any of these paths is smaller than $P(6,0,0,j,1)$. Hence, the largest priority on the path from $a_i^{1,j}$ to $r^j$ is the priority $P(6,0,0,j,1)$ on the vertex $a_i^{1,j}$, and since this is an odd priority, we have $\text{Val}^\sigma(a_i^{1,j}) \subseteq \text{Val}^\sigma(r^j)$.

- If $B_i = 1$, then $\sigma(d_i^{1,j}) = e_i^{1,j}$ and Lemma B.6 then implies $\text{Br}(\sigma)(e_i^{1,j}) = h_i^{1,j}$. So, the path that starts at $e_i^{1,j}$ and follows $\sigma$ passes through $e_i^{1,j}$, $h_i^{1,j}$, $h_{i,2}^{1,j}$, and then arrives at $r^j$. The largest priority on this path is $P(6,0,1,j,0) > P(6,0,0,j,1)$ on the state $h_i^{1,j}$, so we have $\text{Val}^\sigma(r^j) \subseteq \text{Val}^\sigma(e_i^{1,j})$.

Hence, the base case of the induction has been shown. The inductive step will be split into two cases, based on whether $i$ is a $\text{Not}$-gate or an $\text{Or}$-gate.

Suppose that the inductive hypothesis holds for all gates $i$ with $d(i) < k$, and let $i$ be a $\text{Or}$-gate with $d(i) = k$. We must prove three cases.

- The first two cases use the same proof. If $m \leq d(i) + 2$, or if $m > d(i) + 2$ and $\text{Eval}(B,i) = 0$, then by definition we have $\sigma(o_i^l) = r^j$. Since the priority assigned to $o_i^l$ is odd, we have $\text{Val}^\sigma(o_i^l) \subseteq \text{Val}^\sigma(r^j)$.

- If $m > d(i) + 2$ and $\text{Eval}(B,i) = 1$, then by definition we have that $\sigma(o_i^l) = \text{InputState}(i,j,l)$ for some gate $l$ with $l \in \{1,2\}$, and we know that $\text{Eval}(B,I_l(i)) = 1$. Hence, we can apply the inductive hypothesis to argue that $\text{MaxDiff}^\sigma(r^j, \text{InputState}(i,j,l))$ is even, and it satisfies:

$$P(6,0,0,0,0) \leq \text{MaxDiff}^\sigma(r^j, \text{InputState}(i,j,l)) \leq P(6,1,1,0,0).$$

Since the priority assigned to $o_i^l$ is smaller than $P(6,0,0,0,0)$, we have that the same two properties apply to $\text{MaxDiff}^\sigma(r^j, o_i^l)$. Hence, $\text{Val}^\sigma(r^j) \subseteq \text{Val}^\sigma(o_i^l)$, and the required bounds on $\text{MaxDiff}^\sigma(r^j, o_i^l)$ hold because $P(6,1,1,0,0) < P(6,1,1,0,0)$.

Now suppose that the inductive hypothesis holds for all gates $i$ with $d(i) < k$, and let $i$ be a $\text{Not}$-gate with $d(i) = k$. We must prove three cases.

- If $m \leq d(i) + 2$, then by definition, the path that starts at $o_i^l$ and follows $\sigma$ passes through $e_i^l$, and Lemma B.4 implies that it then moves to $d_i^l$, a vertex of the form $a_{i,j}^l$, a number of vertices of the form $b_{j,1}^l$, before finally arriving at $r^j$. It can easily be verified that the largest priority on this path is $P(6,i,0,j,1)$ from the vertex $o_i^l$. So, we have $\text{MaxDiff}^\sigma(r^j, o_i^l) = P(6,i,0,j,1)$, and since this priority is odd, we have $\text{Val}^\sigma(o_i^l) \subseteq \text{Val}^\sigma(r^j)$.

- If $m > d(i) + 2$ and $\text{Eval}(B,i) = 0$, then we must have $\text{Eval}(B,I_l(i)) = 1$. Hence, by definition, the path that starts at $o_i^l$ and follows $\sigma$ first passes through $e_i^l$, and then
Lemma B.4 implies that it then passes through $d_i^j$, and then some vertex of the form $a_i^j$, followed by a number of vertices of the form $t_{i,j}^i$, before finally arriving at $t_{i,d(i)}^i$ and then moving to InputState$(i, j)$. The largest priority on this path is $P(6, i, 0, j, 1)$ from the vertex $a_i^j$. By the inductive hypothesis, we have $\text{MaxDiff}^\sigma(r^j, \text{InputState}(i, j)) < P(6, I(i), 1, j, 0)$, and since $I(i) < i$ we have that $P(6, i, 0, j, 1) > P(6, I(i), 1, j, 0)$. Hence, we have that $\text{MaxDiff}^\sigma(r^j, a_i^j) = P(6, i, 0, j, 1)$, and since this is odd, we have that $\text{Val}^\sigma(a_i^j) \supset \text{Val}^\sigma(r^j)$, as required.

- If $m > d(i) + 2$ and Eval$(B, i) = 1$, then by definition we have that the path that starts at $a_i^j$ and follows $\sigma$ passes through $e_i^j$, and then Lemma B.4 implies that it passes through $h_i^j$, and then reaches $r^j$. The largest priority on this path is $P(6, i, 1, j, 0)$ on the vertex $h_i^j$. Hence we have $\text{MaxDiff}^\sigma(r^j, a_i^j) \leq P(6, i, 1, j, 0)$, and since this priority is even, we have that $\text{Val}^\sigma(r^j) \supset \text{Val}^\sigma(a_i^j)$. Hence, we have shown both of the required properties for this case.

Now that we have shown the two versions of the inductive hypothesis, we have completed the proof.

\[ \square \]

\section*{Appendix C. OR gates}

The following pair of lemmas show that the states $a_i^j$ in the OR gate gadgets correctly switch to the outgoing edge specified by $\chi^{B,K,j}_{m+1}$. The first lemma considers the case where $1 \leq m < \text{Delay}(j, K) - 1$, and the second lemma considers the case where $m = \text{Delay}(j, K) - 1$.

\begin{lemma}
Let $\sigma$ be a strategy that agrees with $\chi^{B,K,j}_m$ for some $K, B \in \{0, 1\}^n$, some $j \in \{0, 1\}^n$, and some $m$ in the range $1 \leq m < \text{Delay}(j, K) - 1$. For each OR-gate $i$, greedy all-switches strategy improvement will switch $a_i^j$ to $\chi^{B,K,j}_{m+1}(a_i^j)$.
\end{lemma}

\begin{proof}
In this proof we will show that the most appealing edge is the one that is specified in Equation (4.1). This boils down to a case analysis.

First suppose that $m < d(i) + 2$. We must prove that the edge to $r^j$ is the most appealing edge at $a_i^j$. By Lemma A.1, we have that $\text{Val}^\sigma(s^j) \subset \text{Val}^\sigma(r^j)$. Furthermore, since $d(I_1(i)) = d(I_2(i)) = d(i) - 1$, part 1 of Lemma B.8 implies that $\text{Val}^\sigma(\text{InputState}(i, j, l)) \subset \text{Val}^\sigma(r^j)$ for $l \in \{1, 2\}$. Hence, we have that $r^j$ is the most appealing edge at $a_i^j$, as required.

Now suppose that $d(i) + 2 \leq m \leq \text{Delay}(j, K) - 1$. There are three cases to consider.

- If both input gates are false, then Lemma A.1 and part 2 of Lemma B.8 imply that $r^j$ will continue to be the most appealing edge at $a_i^j$, as required.
- If $I_l(i)$ is true and $I_{1-l}(i)$ is false, for some $l \in \{1, 2\}$, then part 3 of Lemma B.8 implies that $\text{Val}^\sigma(r^j) \subset \text{Val}^\sigma(\text{InputState}(i, j, l))$, and $\text{Val}^\sigma(\text{InputState}(i, j, l)) \subset \text{Val}^\sigma(r^j)$. Therefore, the most appealing edge at $a_i^j$ is the one to InputState$(i, j, l)$, as required.
- Finally, if both input gates are true, then Lemma B.8 implies that the highest appeal edge at $a_i^j$ is either InputState$(i, j, 1)$ or InputState$(i, j, 2)$. Since OrNext$(i, B, m)$ is defined to be the successor with highest appeal, we have that the highest appeal edge at $a_i^j$ is the one to $a_{I_{\text{OrNext}}(i, B, m)}^j$, as required.

This completes the proof that greedy all-switches strategy improvement will switch $a_i^j$ to $\chi^{B,K,j}_{m+1}(a_i^j)$. \[ \square \]
Lemma C.2. Let $\sigma$ be a strategy that agrees with $\chi_{m}^{B,K,j}$ for some $K, B \in \{0,1\}^n$, some $j \in \{0,1\}^n$, and for $m = \text{Delay}(j, K) - 1$. For each OR-gate $i$, greedy all-switches strategy improvement will switch $s_i^{1-j}$ to $\chi_{m+1}^{B,K,j}(o_i^{1-j})$.

Proof. We must show that the edge to $s_i^{1-j}$ is the most appealing edge at $o_i^{1-j}$. It can be verified that all paths starting at $\text{InputState}(i,j,1)$ and $\text{InputState}(i,j,2)$ either reach $r^{1-j}$, $s_i^{1-j}$, or $r^j$. Furthermore, the largest possible priority on these paths is strictly smaller than $P(7,0,0,0,0)$. Hence, we can apply part 1 of Lemma A.1 and part 1 of Lemma A.2 to conclude that the edge to $s_i^{1-j}$ is the most appealing outgoing edge at $o_i^{1-j}$.

Appendix D. The states $t_{i,l}^j$ in Not gates

In this section we show that the states $t_{i,l}^j$ in the Not gate gadgets correctly switch to the outgoing edge specified by $\chi_{m+1}^{B,K,j}$. The first two lemmas consider the case where $1 \leq m < \text{Delay}(j, K) - 1$, and the third lemma considers the case where $m = \text{Delay}(j, K) - 1$. The first lemma deals with the case where $l < d(i)$, while the second lemma deals with the case where $l > d(i)$. Observe that there is no need to deal with the case where $l = d(i)$, because $t_{i,l}^j$ only has one outgoing edge.

Lemma D.1. Let $\sigma$ be a strategy that agrees with $\chi_{m}^{B,K,j}$ for some $K, B \in \{0,1\}^n$, some $j \in \{0,1\}^n$, and some $m$ in the range $1 \leq m < \text{Delay}(j, K) - 1$. For each Not-gate $i$, and each $l$ in the range $1 \leq l < d(i)$, greedy all-switches strategy improvement will switch $t_{i,l}^j$ to $\chi_{m+1}^{B,K,j}(t_{i,l}^j)$.

Proof. Lemma A.1 implies that the state $t_{i,l}^j$ will not switch to $s_i^j$. In the rest of this proof we consider the two remaining outgoing edges at this state. We have two cases to consider.

1. We first deal with the case where $m < l + 1$, where we must show that the edge to $r^j$ is the highest appeal edge at $t_{i,l}^j$. Let $v = \sigma(t_{i,l}^j)$ be the successor of $t_{i,l}^j$ according to $\sigma$ (if $m = 1$ then $v = s_i^j$, and otherwise $v = r^j$). Since $m \leq l$, the definition in Equation (4.2) we have that $\sigma(t_{i,l-1}^j) = v$. Since the priority assigned to $t_{i,l-1}^j$ is odd, we therefore have that $\text{Val}^\sigma(t_{i,l-1}^j) \sqsubseteq \text{Val}^\sigma(v)$. Since we already know from Lemma A.1 that $\text{Val}^\sigma(s_i^j) \sqsubseteq \text{Val}^\sigma(r^j)$, we have therefore proved that the edge to $r^j$ is the most appealing edge at $t_{i,l}^j$.

2. Now we deal with the case where $m \geq l + 1$, where we must show that the most appealing edge at $t_{i,l}^j$ is the one to $t_{i,l-1}^j$. Since $m > l$, the definition in Equation (4.2) implies that the path that starts at $t_{i,l-1}^j$ and follows $\sigma$ will pass through $t_{i,l'}^j$ for all $l'$ in the range $0 \leq l' < l$ before arriving at $r^j$. The highest priority on this path is $P(5, i, 2k+4n+4, j, 0)$ on the vertex $t_{i,0}^j$. Since this priority is even we have that $\text{Val}^\sigma(r^j) \sqsubseteq \text{Val}^\sigma(t_{i,l}^j)$, and therefore the edge to $t_{i,l-1}^j$ is the most appealing edge at $t_{i,l}^j$.

Lemma D.2. Let $\sigma$ be a strategy that agrees with $\chi_{m}^{B,K,j}$ for some $K, B \in \{0,1\}^n$, some $j \in \{0,1\}^n$, and some $m$ in the range $1 \leq m < \text{Delay}(j, K) - 1$. For each Not-gate $i$, and each $l > d(i)$, greedy all-switches strategy improvement will switch $t_{i,l}^j$ to $\chi_{m+1}^{B,K,j}(t_{i,l}^j)$.
Proof. Lemma A.1 implies that the state $t_{i,l}^j$ will not switch to $s^j$. In the rest of this proof we consider the two remaining outgoing edges at this state.

(1) First we deal with the case where $m < l + 1$, where we must show that the edge to $r^j$ is the most appealing edge at $t_{i,l}^j$. When $l > d(i) + 1$, the proof of this fact is identical to Item 1 in the proof of Lemma D.1. For $l = d(i) + 1$, we invoke Lemma B.8 to argue that, since $m < l + 1 = d(i) + 2$, we have that $\text{Val}^\sigma(\sigma_i^j) \subseteq \text{Val}^\sigma(r^j)$. Since the priority assigned to $t_{i,d(i)}^j$ is odd, we therefore also have that $\text{Val}^\sigma(t_{i,d(i)}^j) \subseteq \text{Val}^\sigma(r^j)$. Therefore, the edge to $r^j$ is the most appealing edge at $t_{i,d(i)+1}^j$.

(2) Now we deal with the case where $m \geq l + 1$, and where $\text{Eval}(B, I(i)) = 0$. Here we must show that the edge to $r^j$ is the most appealing edge at $t_{i,l}^j$. For each $l > d(i) + 1$, the proof is identical to the proof of the first case in the proof of this lemma. For $l = d(i) + 1$, we invoke Lemma B.8 to argue that, since $\text{Eval}(B, I(i)) = 0$ we must have $\text{Val}^\sigma(\sigma_i^j) \subseteq \text{Val}^\sigma(r^j)$, and therefore the edge to $r^j$ is the most appealing edge at $t_{i,l}^j$.

(3) Finally, we deal with the case where $m \geq l + 1$ and where $\text{Eval}(B, I(i)) = 1$. Here we must show that edge to $t_{i,l-1}^j$ is the most appealing edge at $t_{i,l}^j$. From the definition given in Equation (4.2), we have that the path that starts at $t_{i,l-1}^j$ and follows $\sigma$ will pass through $t_{i,l'}^j$ for each $l'$ in the range $d(i) \leq l' < l$ before moving to $\sigma_i^j(l)$. Since $m \geq l + 1 > d(i)$, we have that $m \geq d(i) + 2$, and therefore Lemma B.8 implies that $\text{Val}^\sigma(r^j) \subseteq \text{Val}^\sigma(\sigma_i^j)$ and that $\text{MaxDiff}^\sigma(r^j, \sigma_i^j) \geq \text{P}(6,0,0,0,0)$. All priorities on the path from $t_{i,l-1}^j$ to $\sigma_i^j(l)$ are smaller than $\text{P}(6,0,0,0,0)$, so we can conclude that $\text{Val}^\sigma(r^j) \subseteq \text{Val}^\sigma(t_{i,l-1}^j)$, as required.

\[ \text{Lemma D.3.} \text{ Let } \sigma \text{ be a strategy that agrees with } \chi_m^{B,K,j} \text{ for some } K, B \in \{0,1\}^n, \text{ some } j \in \{0,1\}^n, \text{ and for } m = \text{Delay}(j, K) - 1. \text{ For each NOT-gate } i, \text{ and each } l \text{ in the range } 1 \leq l \leq 2k + 4n + 6, \text{ greedy all-switches strategy improvement will switch } t_{i,l}^{1-j} \text{ to } \chi_{m+1}^{B,K,j}(t_{i,l}^{1-j}). \]

Proof. We must show that the edge to $s^{1-j}$ is the most appealing edge at $t_{i,l}^{1-j}$. It can be verified that all paths starting at $t_{i,l-1}^{1-j}$ reach one of $r^{1-j}$, $s^{1-j}$, or $r^j$. Furthermore, the largest possible priority on these paths is strictly smaller than $\text{P}(7,0,0,0,0)$. Hence, we can apply part 1 of Lemma A.1 and part 1 of Lemma A.2 to conclude that the edge to $s^{1-j}$ is the most appealing outgoing edge at $t_{i,l}^{1-j}$.

Appendix E. The state $d_i^j$ in NOT gates

In this section we show that the states $d_i^j$ in the NOT gate gadgets correctly switch to the outgoing edge specified by $\chi_m^{B,K,j}$. The first lemma considers the case where $m = 1$, the second lemma considers the case where $m = 2$, the third lemma considers the case where $3 \leq m < d(i) + 2$, the fourth lemma considers the case where $d(i) + 2 \leq m < \text{Delay}(j, K) - 1$ and the gate outputs 0, the fifth lemma considers the case where $d(i) + 2 \leq m < \text{Delay}(j, K)$ and the gate outputs 1, and the final lemma considers the case where $m = \text{Delay}(j, K) - 1$. 
Lemma E.1. Let $\sigma$ be a strategy that agrees with $\chi^{B,K,j}_m$ for some $K, B \in \{0,1\}^n$, and where $m = 1$. For each NOT-gate $i$, greedy all-switches strategy improvement will switch $d^j_i$ to $\chi^{B,K,j}_{m+1}(d^j_i)$.

Proof. According to the definition given in Equation (4.4), we must show that the edge to $r^j$ is the most appealing edge at $d^j_i$. We do so by a case analysis.

1. First we consider the vertex $s^j$. Here we can apply part 2 of Lemma A.1 to argue that $\text{Val}^\sigma(s^j) \subset \text{Val}^\sigma(r^j)$.

2. Next we consider a vertex $a^j_{i,l}$ with $l \neq d(i)$. Here the definition given in Equation (4.2) implies that the path that starts at $a^j_{i,l}$ and follows $\sigma$ passes through $t^j_{i,l}$ and then arrives at $s^j$. The largest priority on this path is $P(5,i,l+1,j,0)$ on the vertex $a^j_{i,l}$. However, since this priority is smaller than $P(7,0,0,0,0)$, we can apply part 2 of Lemma A.1 to prove that $\text{Val}^\sigma(a^j_{i,l}) \subset \text{Val}^\sigma(r^j)$.

3. Next we consider a vertex $a^j_{i,l}$ with $l = d(i)$. Here we can apply Lemma B.7 to argue that $\text{Val}^\sigma(a^j_{i,d(i)}) \subset \text{Val}^\sigma(r^j)$. Furthermore, the largest priority on the path from $a^j_{i,d}$ to $s^j$ is the odd priority on $t^j_{i,d(i)}$. Hence, we can conclude that $\text{Val}^\sigma(a^j_{i,d(i)}) \subset \text{Val}^\sigma(r^j)$.

4. Finally, we consider the vertex $e^j_{i,l}$. Lemma B.4 implies that $\text{Br}(\sigma)(e^j_{i,l}) = d^j_i$. Hence, the path that starts at $e^j_{i,l}$ moves to $d^j_i$ and then to $s^j$. The highest priority on this path is $P(4,i,1,j,0) < P(7,0,0,0,0)$. Therefore, we can apply Lemma A.1 to show that $\text{Val}^\sigma(e^j_{i,l}) \subset \text{Val}^\sigma(r^j)$.

Hence, we have shown that the edge to $r^j$ is the most appealing outgoing edge at $d^j_i$, so greedy all-switches strategy improvement will switch $d^j_i$ to $r^j$.\qed

Lemma E.2. Let $\sigma$ be a strategy that agrees with $\chi^{B,K,j}_m$ for some $K, B \in \{0,1\}^n$, and where $m = 2$. For each NOT-gate $i$, greedy all-switches strategy improvement will switch $d^j_i$ to $\chi^{B,K,j}_{m+1}(d^j_i)$.

Proof. According to the definition given in Equation (4.4), we must show that the edge to $a^j_{i,2k+4n+6}$ is the most appealing edge at $d^j_i$. We do so by a case analysis.

1. First we consider the vertex $r^j$. Observe that the path that starts at $a^j_{i,2k+4n+6}$ and follows $\sigma$ visits $t^j_{i,2k+4n+6}$ and then arrives at $r^j$. The highest priority on this path is the even priority assigned to $a^j_{i,2k+4n+6}$, so therefore we can conclude that $\text{Val}^\sigma(r^j) \subset \text{Val}^\sigma(a^j_{i,2k+4n+6})$.

2. Next we consider the vertex $s^j$. Here we can apply Lemma A.1 to argue that $\text{Val}^\sigma(s^j) \subset \text{Val}^\sigma(r^j)$, and we have already shown that $\text{Val}^\sigma(r^j) \subset \text{Val}^\sigma(a^j_{i,2k+4n+6})$.

3. Next we consider a vertex $a^j_{i,l}$ with $l \neq d(i)$ and $l \neq a^j_{i,2k+4n+6}$. The path that starts at $a^j_{i,l}$ and follows $\sigma$ passes through $t^j_{i,l}$ and then arrives at $r^j$. The largest priority on this path is the even priority assigned to $a^j_{i,l}$. However, since $l < 2k + 4n + 6$, we have that this priority is smaller than the even priority assigned to $a^j_{i,2k+4n+6}$. Therefore, we have $\text{Val}^\sigma(a^j_{i,l}) \subset \text{Val}^\sigma(a^j_{i,2k+4n+6})$.
(4) Next we consider the vertex $a^j_{i,d(i)}$. Here we can apply Lemma B.7 to argue that $\text{Val}^\sigma(a^j_{i,d(i)}) \subseteq \text{Val}^\sigma(r^j)$. Furthermore, the largest priority on the path from $a^j_{i,d(i)}$ to $a^j_i$ is the odd priority on $t^j_{i,d(i)}$. Since the highest priority on the path from $a^j_{i,2k+4n+6}$ to $r^j$ is even, we can conclude that $\text{Val}^\sigma(a^j_{i,d(i)}) \subseteq \text{Val}^\sigma(a^j_{i,2k+4n+6})$.

(5) Finally, we consider the vertex $e^j_i$. Lemma B.4 implies that $\text{Br}(\sigma)(e^j_i) = d^j_i$. Hence, the path that starts at $e^j_i$ moves to $d^j_i$ and then to $r^j$. The highest priority on this path is $P(4, i, j, 0)$ on the vertex $e^j_i$. However, this is smaller than the largest priority on the path from $a^j_{i,2k+4n+6}$ to $r^j$, so we can conclude that $\text{Val}^\sigma(e^j_i) \subseteq \text{Val}^\sigma(a^j_{i,2k+4n+6})$.

Lemma E.3. Let $\sigma$ be a strategy that agrees with $\chi^B_m,K,j$ for some $K, B \in \{0,1\}^n$, some $j \in \{0,1\}^n$, and some $m$ in the range $3 \leq m < d(i) + 2$. For each NOT-gate $i$, greedy all-switches strategy improvement will switch $d^j_i$ to $\chi^B_{m+1}K,j(d^j_i)$.

Proof. Lemma A.1 implies that the state $d^j_i$ will not switch to $s^j$. In the rest of this proof we consider the other outgoing edges at this state. Since we are in the case where $m < d(i) + 2$ the definition from Equation (4.4) specifies that greedy all-switches strategy improvement must switch to $a^j_{i,m-2}$. Hence must argue that the edge to $a^j_{i,m-2}$ is the most appealing edge at $d^j_i$, and we will start by considering the appeal of this edge. The definition in Equation (4.2) implies that the path that starts at $a^j_{i,m-2}$ passes through $t^j_{i,l}$ for all $l \leq m - 2$ before arriving at $r^j$. The highest priority on this path is $P(5, i, 2k + 4n + 4, j, 0)$ on the vertex $t^j_{i,0}$, and the second highest priority on this path is $P(5, i, m - 1, j, 0)$ on the vertex $a^j_{i,m-2}$. We will now show that all other edges are less appealing.

(1) First we consider the vertex $r^j$. Since $P(5, i, 2k + 4n + 4, j, 0)$ is even, we immediately get that $\text{Val}^\sigma(r^j) \subseteq \text{Val}^\sigma(a^j_{i,m-2})$.

(2) Next we consider a vertex $a^j_{i,l}$ with $l < m - 2$. The path that starts at this vertex and follows $\sigma$ passes through $t^j_{i,l}$ for all $l' \leq l$ before arriving at $r^j$. The highest priority on this path is $P(5, i, 2k + 4n + 4, j, 0)$ on the vertex $t^j_{i,0}$, and the second highest priority on this path is $P(5, i, l + 1, j, 0)$ on the vertex $a^j_{i,l}$. Hence, we have that $\text{MaxDiff}^\sigma(a^j_{i,m-2}, a^j_{i,l})$ is $P(5, i, m - 1, j, 0)$, and since this is even, we can conclude that $\text{Val}^\sigma(a^j_{i,l}) \subseteq \text{Val}^\sigma(a^j_{i,m-2})$.

(3) Next we consider a vertex $a^j_{i,l}$ with $l > m - 2$ and with $l \neq d(i)$. The path that starts at this vertex and follows $\sigma$ passes through $t^j_{i,l}$ and then moves immediately to $r^j$. The highest priority on this path is $P(5, i, l + 1, j, 0)$ on the vertex $a^j_{i,l}$. Since $l + 1 < 2k + 4n + 4$ we have that $\text{MaxDiff}^\sigma(a^j_{i,m-2}, a^j_{i,l})$ is $P(5, i, 2k + 4n + 4, j, 0)$, and since this priority is even, we can conclude that $\text{Val}^\sigma(a^j_{i,l}) \subseteq \text{Val}^\sigma(a^j_{i,m-2})$.

(4) Next we consider the vertex $a^j_{i,d(i)}$. The path that starts at this vertex passes through $t^j_{i,d(i)}$, and then moves to InputState($i, j$). Since $m < d(i) + 2$, we have that $m \leq d(I(i)) + 2$, and therefore the first case of Lemma B.8 tells us that $\text{Val}^\sigma(\text{InputState}(i, j)) \subseteq \text{Val}^\sigma(r^j)$. Hence we can conclude that $\text{Val}^\sigma(a^j_{i,d(i)}) \subseteq \text{Val}^\sigma(a^j_{i,m-2})$. 

THE COMPLEXITY OF ALL-SWITCHES STRATEGY IMPROVEMENT 51
Therefore, we have shown that the edge to $a_{i,m-2}^j$ is the most appealing outgoing edge at $d_i^j$, and so this edge will be switched by greedy all-switches strategy improvement.

Lemma E.4. Let $\sigma$ be a strategy that agrees with $\chi^{B,K,j}_m$ for some $K, B \in \{0,1\}^n$, some $j \in \{0,1\}^n$, and some $m$ in the range $d(i) + 2 \leq m < \text{Delay}(j,K) - 1$. For each Not-gate $\text{Eval}(B, I(i)) = 1$ then greedy all-switches strategy improvement will switch $d_i^j$ to $\chi^{B,K,j}_{m+1}(d_i^j)$.

Proof. Lemma A.1 implies that the state $d_i^j$ will not switch to $s^j$. In the rest of this proof we consider the other outgoing edges at this state.

Since we are in the case where $m \geq d(i) + 2$ and $\text{Eval}(B, I(i)) = 1$, the definition from Equation (4.4) specifies that greedy all-switches strategy improvement must switch to $a_{i,m-2}^j$.

Hence must argue that the edge to $a_{i,m-2}^j$ is the most appealing edge at $d_i^j$, and we will start by considering the appeal of this edge. The definition in Equation (4.2) implies that the path that starts at $a_{i,m-2}^j$, passes through $t_{i,l}$, and so this edge will be switched by greedy all-switches strategy improvement.

Proof. Lemma A.1 implies that the state $d_i^j$ will not switch to $s^j$. In the rest of this proof we consider the other outgoing edges at this state.

Since we are in the case where $m \geq d(i) + 2$ and $\text{Eval}(B, I(i)) = 1$, the definition from Equation (4.4) specifies that greedy all-switches strategy improvement must switch to $a_{i,m-2}^j$.

Hence must argue that the edge to $a_{i,m-2}^j$ is the most appealing edge at $d_i^j$, and we will start by considering the appeal of this edge. The definition in Equation (4.2) implies that the path that starts at $a_{i,m-2}^j$, passes through $t_{i,l}$, and so this edge will be switched by greedy all-switches strategy improvement.

Proof. Lemma A.1 implies that the state $d_i^j$ will not switch to $s^j$. In the rest of this proof we consider the other outgoing edges at this state.

Since we are in the case where $m \geq d(i) + 2$ and $\text{Eval}(B, I(i)) = 1$, the definition from Equation (4.4) specifies that greedy all-switches strategy improvement must switch to $a_{i,m-2}^j$.

Hence must argue that the edge to $a_{i,m-2}^j$ is the most appealing edge at $d_i^j$, and we will start by considering the appeal of this edge. The definition in Equation (4.2) implies that the path that starts at $a_{i,m-2}^j$, passes through $t_{i,l}$, and so this edge will be switched by greedy all-switches strategy improvement.

Therefore, we have shown that the edge to $a_{i,m-2}^j$ is the most appealing outgoing edge at $d_i^j$, and so this edge will be switched by greedy all-switches strategy improvement.

Lemma E.5. Let $\sigma$ be a strategy that agrees with $\chi^{B,K,j}_m$ for some $K, B \in \{0,1\}^n$, some $j \in \{0,1\}^n$, and some $m$ in the range $d(i) + 2 \leq m < \text{Delay}(j,K) - 1$. For each Not-gate $\text{Eval}(B, I(i)) = 0$ then greedy all-switches strategy improvement will switch $d_i^j$ to $\chi^{B,K,j}_{m+1}(d_i^j)$.
Proof. Lemma A.1 implies that the state $d_i^j$ will not switch to $s_i^j$. In the rest of this proof we consider the other outgoing edges at this state.

Since $m \geq d(i) + 2$ and $\text{Eval}(B, I(i) = 0)$, the definition in Equation (4.4) specifies that the edge to $e_i^j$ is the most appealing edge at $d_i^j$. To prove this, we first show that all other edges are less appealing than $a_{i,d(i)-1}^j$, and we will then later show that $e_i^j$ is more appealing than $a_{i,d(i)-1}^j$. The definition in Equation (4.2) implies that the path that starts at $a_{i,d(i)-1}^j$ passes through $t_{i,j}^l$ for all $l$ in the range $0 \leq l \leq d(i) - 1$ before arriving at $r_i^j$. The largest priority on this path is $P(5, i, d(i), j0)$ on the state $a_{i,d(i)-1}^j$. We now consider the other outgoing edges.

(1) First we consider the vertex $r_i^j$. Since $P(5, i, 2k + 4n + 4, j0)$ is even, we immediately get that $\text{Val}^\sigma(r_j) \subseteq \text{Val}^\sigma(a_{i,m-2}^j)$.

(2) Next we consider a vertex $a_{i,l}^j$ with $l < d(i) - 1$. Here we can use the same reasoning as we used in Item 2 in the proof of Lemma E.3 to argue that $\text{Val}^\sigma(a_{i,l}^j) \supseteq \text{Val}^\sigma(a_{i,d(i)-1}^j)$.

(3) Next we consider a vertex $a_{i,l}^j$ with $l > d(i)$. Here we can use the same reasoning as we used in Item 3 in the proof of Lemma E.3 to argue that $\text{Val}^\sigma(a_{i,1}^j) \supseteq \text{Val}^\sigma(a_{i,d(i)-1}^j)$.

(4) Finally, we consider the vertex $a_{i,d(i)}^j$. Here we can use the same reasoning as we used in Item 4 in the proof of Lemma E.3 to argue that $\text{Val}^\sigma(a_{i,d(i)}^j) \supseteq \text{Val}^\sigma(a_{i,d(i)-1}^j)$, although this time we will use case two of Lemma B.8.

So, we have shown that every edge other than the one to $e_i^j$ is less appealing than the edge to $a_{i,d(i)-1}^j$.

Now we will show that the edge to $e_i^j$ is more appealing than the edge to $a_{i,d(i)-1}^j$. There are two cases to consider.

- If $m = d(i) + 2$, then $\sigma(d_i^j) = a_{i,d(i)-1}^j$. Since Lemma B.4 implies that $\text{Br}(\sigma)(e_i^j) = d_i^j$, we have that the path that starts at $e_i^j$ and follows $\sigma$ passes through $d_i^j$ and then arrives at $a_{i,d(i)-1}^j$. The largest priority on this path is $P(4, i, 1, j0)$, and since this is even, we can conclude that $\text{Val}^\sigma(a_{i,d(i)-1}^j) \supseteq \text{Val}^\sigma(e_i^j)$.

- If $m > d(i) + 2$, then $\sigma(d_i^j) = e_i^j$. In this case Lemma B.4 implies that $\text{Br}(\sigma)(e_i^j) = h_i^j$. The path that starts at $e_i^j$ and follows $\sigma$ passes through $h_i^j$ and then moves directly to $r_i^j$. The largest priority on this path is $P(6, i, 1, j0)$, which is bigger than $P(5, i, d(i), j0)$. Therefore, $\text{MaxDiff}^\sigma(e_i^j, a_{i,d(i)-1}^j) = P(6, i, 1, j0)$, and since this is even, we can conclude that $\text{Val}^\sigma(a_{i,d(i)-1}^j) \supseteq \text{Val}^\sigma(e_i^j)$.

Hence, we have shown that the edge to $e_i^j$ is the most appealing edge at $d_i^j$. 

Lemma E.6. Let $\sigma$ be a strategy that agrees with $\chi_m^{B,K,j}$ for some $K, B \in \{0,1\}^n$, some $j \in \{0,1\}^n$, and for $m = \text{Delay}(j,K) - 1$. For each Not-gate $i$ greedy all-switches strategy improvement will switch $d_i^{1-j}$ to $\chi_m^{B,K,j}(d_i^{1-j})$.

Proof. We must show that the edge to $s_i^{1-j}$ is the most appealing edge at $d_i^{1-j}$. It can be verified that all paths starting at the vertices $a_{i,l}^{1-j}$ and $e_i^j$ reach one of $r^{1-j}$, $s_i^{1-j}$, or $r^j$. Furthermore, the largest possible priority on all of these paths is strictly smaller than
P(7, 0, 0, 0, 0). Hence, we can apply part 1 of Lemma A.1 and part 1 of Lemma A.2 to conclude that the edge to \( s^{1-j} \) is the most appealing outgoing edge at \( d_i^{1-j} \).

\[ \square \]

**APPENDIX F. THE VERTEXES \( z^j \)**

In this section we show that the states \( z^j \) correctly switch to the outgoing edge specified by \( \chi_{m+1}^{B,K,j} \). The first lemma considers the case where \( l = j \), while the second lemma considers the case where \( l = 1 - j \).

**Lemma F.1.** Let \( \sigma \) be a strategy that agrees with \( \chi_{m}^{B,K,j} \) for some \( K, B \in \{0, 1\}^n \), some \( j \in \{0, 1\}^n \), and \( m \) in the range \( 1 \leq m \leq \text{Delay}(j, K) - 1 \). The greedy all-switches strategy improvement algorithm will switch \( z^j \) to \( \chi_{m+1}^{B,K,j}(z^j) \).

**Proof.** We must show that the edge to \( r^j \) is the most appealing edge at \( z^j \). This follows immediately from part 2 of Lemma A.1.

**Lemma F.2.** Let \( \sigma \) be a strategy that agrees with \( \chi_{m}^{B,K,j} \) for some \( K, B \in \{0, 1\}^n \), some \( j \in \{0, 1\}^n \), and some \( m \) in the range \( 1 \leq m \leq \text{Delay}(j, K) - 1 \). The greedy all-switches strategy improvement algorithm will switch \( z^{1-j} \) to \( \chi_{m+1}^{B,K,j}(z^{1-j}) \).

**Proof.** There are two cases to consider.
1. If \( m < \text{Delay}(j, K) - 1 \), then we must show that the edge to \( r^{1-j} \) is the most appealing edge at \( z^{1-j} \). This follows immediately by applying part 2 of Lemma A.1.
2. If \( m = \text{Delay}(j, K) - 1 \), then since \( \text{Delay}(j, K) + \text{Delay}(1 - j, K) = \text{Length}(K) \), we must show that the edge to \( s^{1-j} \) is the most appealing edge at \( z^{1-j} \). This follows immediately from part 1 of Lemma A.1.

\[ \square \]

**APPENDIX G. THE VERTEXES \( y^j \)**

In this section we show that the states \( y^j \) correctly switch to the outgoing edge specified by \( \chi_{m+1}^{B,K,j} \). The first lemma considers the case where \( l = j \), while the second lemma considers the case where \( l = 1 - j \).

**Lemma G.1.** Let \( \sigma \) be a strategy that agrees with \( \chi_{m}^{B,K,j} \) for some \( K, B \in \{0, 1\}^n \), some \( j \in \{0, 1\}^n \), and some \( m \) in the range \( 1 \leq m \leq \text{Delay}(j, K) - 1 \). The greedy all-switches strategy improvement algorithm will switch \( y^j \) to \( \chi_{m+1}^{B,K,j}(y^j) \).

**Proof.** The definition of \( \chi_{m+1}^{B,K,j}(y^j) \) specifies that the edge chosen at \( y^j \) is defined by \( \sigma_{m+\text{Delay}(j,K)}(y^j) \), which is given in Equation (4.7). According to this definition, we must show that the edge to \( r^j \) is the most appealing outgoing edge at \( y^j \). This follows immediately from parts 1 and 2 of Lemma A.2.

**Lemma G.2.** Let \( \sigma \) be a strategy that agrees with \( \chi_{m}^{B,K,j} \) for some \( K, B \in \{0, 1\}^n \), some \( j \in \{0, 1\}^n \), and some \( m \) in the range \( 1 \leq m \leq \text{Delay}(j, K) - 1 \). The greedy all-switches strategy improvement algorithm will switch \( y^{1-j} \) to \( \chi_{m+1}^{B,K,j}(y^{1-j}) \).

**Proof.** According to Equation (4.7), we must show that the edge to \( r^j \) is the most appealing edge at \( y^{1-j} \). This follows immediately from Lemma A.2.

\[ \square \]
APPENDIX II. THE VERTICES \( p^j_l \)

In this section we show that the vertices \( p^j_l \) correctly switch to the outgoing edge specified by \( \chi^{B,K,j}_{m+1} \). The first lemma considers the case where \( l = j \), while the second lemma considers the case where \( l = 1 - j \).

**Lemma H.1.** Let \( \sigma \) be a strategy that agrees with \( \chi^{B,K,j}_m \) for some \( K, B \in \{0, 1\}^n \), some \( j \in \{0, 1\}^n \), and some \( m \) in the range \( 1 \leq m \leq \text{Delay}(j, K) - 1 \). For each \( i \in \text{Input/Output} \), the greedy all-switches strategy improvement algorithm will switch \( p^j_l \) to \( \chi^{B,K,j}_{m+1}(p^j_l) \).

**Proof.** Since \( m \) is in the range \( 1 \leq m \leq \text{Delay}(j, K) - 1 \), the definition given in Equation (4.8) specifies that \( o^j_{I(i)} \) should be the most appealing outgoing edge at \( p^j_l \). There are two cases to consider.

1. If \( m = 1 \), then observe that the path that starts at \( o^j_{I(i)} \) and follows \( \sigma \) will eventually reach \( s^j \), no matter whether \( I(i) \) is a \( \text{Not} \)-gate or an \( \text{Or} \)-gate. Furthermore, the largest priority on this path is strictly smaller than \( P(7, 0, 0, 0, 0) \). On the other hand, the path that starts at \( p^j_{1,1} \) moves immediately to \( r^{1-j} \), and the largest priority on this path is strictly smaller than \( P(7, 0, 0, 0, 0) \). Hence, we can apply part 2 of Lemma A.2 to argue that \( \text{Val}^\sigma(p^j_{1,1}) \sqsubseteq \text{Val}^\sigma(o^j_{I(i)}) \), as required.

2. If \( m \geq 1 \), then then observe that the path that starts at \( o^j_{I(i)} \) and follows \( \sigma \) will eventually reach \( r^j \), and again the largest priority on this path is strictly smaller than \( P(7, 0, 0, 0, 0) \). Hence, we can apply part 2 of Lemma A.2 to argue that \( \text{Val}^\sigma(p^j_{1,1}) \sqsubseteq \text{Val}^\sigma(o^j_{I(i)}) \), as required. \( \square \)

**Lemma H.2.** Let \( \sigma \) be a strategy that agrees with \( \chi^{B,K,j}_m \) for some \( K, B \in \{0, 1\}^n \), some \( j \in \{0, 1\}^n \), and some \( m \) in the range \( 1 \leq m \leq \text{Delay}(j, K) - 1 \). For each \( i \in \text{Input/Output} \), the greedy all-switches strategy improvement algorithm will switch \( p^j_{1-j} \) to \( \chi^{B,K,j}_{m+1}(p^j_{1-j}) \).

**Proof.** The definition given in Equation (4.8) specifies that the edge to \( p^j_{1-j} \) should be the most appealing edge at \( p^j_{1-j} \). The path that starts at \( o^j_{I(i)} \) and follows \( \sigma \) must eventually arrive at either \( s^{1-j} \) or \( r^{1-j} \). In particular, observe that \( r^j \) cannot be reached due to the vertices \( q^j_{0,0} \), which by Lemma B.2 selects the edge towards \( q^j_{1,1} \). On the other hand, the path that starts at \( p^j_{1-j} \) moves directly to \( r^j \). Moreover the largest priorities on both of these paths are strictly smaller than \( P(7, 0, 0, 0, 0) \). Hence, we can apply Lemmas A.1 and A.2 to argue that \( \text{Val}^\sigma(o^j_{I(i)}) \sqsubseteq \text{Val}^\sigma(r^j) \). \( \square \)

APPENDIX I. THE VERTICES \( h^l_{i,0} \)

In this section we show that the vertices \( h^l_{i,0} \) correctly switch to the outgoing edge specified by \( \chi^{B,K,j}_{m+1} \). The first lemma considers the case where \( l = j \), while the second lemma considers the case where \( l = 1 - j \).

**Lemma I.1.** Let \( \sigma \) be a strategy that agrees with \( \chi^{B,K,j}_m \) for some \( K, B \in \{0, 1\}^n \), some \( j \in \{0, 1\}^n \), and some \( m \) in the range \( 1 \leq m \leq \text{Delay}(j, K) - 1 \). For each \( i \in \text{Input/Output} \), the greedy all-switches strategy improvement algorithm will switch \( h^l_{i,0} \) to \( \chi^{B,K,j}_{m+1}(h^l_{i,0}) \).
Proof. We must show that the most appealing edge at \( h_{i,0}^j \) should be \( h_{i,1}^j \). Observe that both \( h_{i,1}^j \) and \( h_{i,2}^j \) move directly to \( r^j \) and \( r^{1-j} \), respectively. Moreover, the priorities assigned to these vertices are strictly smaller than \( P(7,0,0,0,0) \). Since \( h_{i,1}^j \) moves to \( r^j \), we can apply part 2 of Lemma A.2 to prove that \( h_{i,1}^j \) is the most appealing edge at \( h_{i,0}^j \). □

**Lemma J.2.** Let \( \sigma \) be a strategy that agrees with \( \chi_{m+1}^{B,K,j} \) for some \( K, B \in \{0,1\}^n \), and \( 1 \leq m \leq \text{Delay}(j,K) - 1 \). The greedy all-switches strategy improvement algorithm will switch \( h_{i,0}^{1-j} \) to \( h_{i,0}^{1-j} \).

Proof. We must show that the most appealing edge at \( h_{i,0}^j \) should be \( h_{i,1}^j \). Observe that both \( h_{i,1}^{1-j} \) and \( h_{i,2}^{1-j} \) move directly to \( r^{1-j} \) and \( r^j \), respectively. Moreover, the priorities assigned to these vertices are strictly smaller than \( P(7,0,0,0,0) \). We will use these fact in order to apply Lemma A.2 in the following case analysis. According to Equation (4.9), there are two cases to consider. Since \( h_{i,1}^j \) moves to \( r^j \), we can apply part 2 of Lemma A.2 to prove that \( h_{i,1}^j \) is the most appealing edge at \( h_{i,0}^j \). □

**Appendix J. Input/output gates**

In this section we show that the vertices in the input/output gadgets correctly switch to the outgoing edge specified by \( \chi_{m+1}^{B,K,j} \). The first two lemmas deal with the case where the input/output gadget for circuit \( j \) resets. Note that this occurs one iteration later than the rest of the vertices in circuit \( j \), which is why we prove separate lemmas for this case. Otherwise, the input/output gadgets behave as if they are \( \text{NOT} \) gates, so the proofs that we have already given for the \( \text{NOT} \) gates can be applied with only minor changes. These is formalized in the final two lemmas of this section. The first of these lemmas considers the input/output gadgets in circuit \( j \) and the second considers the input/output gadgets in circuit \( 1 - j \).

**Lemma J.1.** Let \( \sigma \) be a strategy that agrees with \( \chi_{m}^{B,K,j} \) for some \( K, B \in \{0,1\}^n \), and \( m = 1 \). For each input/output-gate \( i \), and each \( l \) in the range \( 1 \leq l < 2k + 4n + 6 \), greedy all-switches strategy improvement will switch \( t_{i,l}^j \) to \( \chi_{m+1}^{B,K,j} (t_{i,l}^j) \).

Proof. We must show that the edge to \( u^j \) is the most appealing edge at \( t_{i,l}^j \). All paths that start at \( t_{i,l}^j \) and follow \( \sigma \) will eventually arrive at \( s^j \), either via \( y^j \), or via \( p_i^j \). On the other hand, the path that starts at \( u^j \) moves directly to \( s^j \). Therefore, part 2 of Lemma A.2 implies that the edge to \( u^j \) is the most appealing edge at \( t_{i,l}^j \). □

**Lemma J.2.** Let \( \sigma \) be a strategy that agrees with \( \chi_{m}^{B,K,j} \) for some \( K, B \in \{0,1\}^n \), and \( m = 1 \). For each input/output-gate \( i \) greedy all-switches strategy improvement will switch \( d_i^j \) to \( \chi_{m+1}^{B,K,j} (d_i^j) \).

Proof. This proof uses the same argument as the proof of Lemma J.1, because all paths that start at \( d_i^j \) will eventually arrive at \( r^{1-j} \). □

**Lemma J.3.** Let \( \sigma \) be a strategy that agrees with \( \chi_{m}^{B,K,j} \) for some \( K, B \in \{0,1\}^n \), and \( j \in \{0,1\}^n \), and \( m \) in the range \( 2 \leq m \leq \text{Delay}(j,K) - 1 \). For each input/output-gate
i, and each \( l \) in the range \( 1 \leq l < 2k + 4n + 6 \), greedy all-switches strategy improvement will switch \( t_{i,l}^j \) to \( \chi_{m+1}^{B,K,j}(t_{i,l}^j) \) and \( d_i^j \) to \( \chi_{m+1}^{B,K,j}(d_i^j) \).

**Proof.** Since \( m \geq 2 \), we have that \( \sigma(y^j_i) = r^j \) and \( \sigma(z^j_i) = s^j \). Hence, both \( t_{i,l}^j \) and \( d_i^j \) behave in exactly the same way as the states \( t_{i,l}^{i'} \) and \( d_i^{i'} \) for \( i' \in \text{NOT} \), with the exception that these states one step behind the NOT-gate vertices, due to the delay introduced by \( y^j \). Note, however, that this is account for by placing the edge to \( t_{i,l}^j \) on \( t_{i,l}^{d(C)} \), rather than \( t_{i,l}^{d(C)+1} \), as would be expected for a NOT-gate with depth \( d(C) + 1 \). Therefore, to prove this lemma, we can use exactly the reasoning as gave for Lemmas D.1, D.2, E.1, E.2, E.3, E.5, and E.4. This is because all of the reasoning used there is done relative to \( r^j \) and \( s^j \), and since \( y^j \) and \( z^j \) have insignificant priorities, none of this reasoning changes. \( \square \)

**Lemma J.4.** Let \( \sigma \) be a strategy that agrees with \( \chi_{m}^{B,K,j} \) for some \( K, B \in \{0,1\}^n \), and for \( m \) in the range \( 2 \leq m < \text{Delay}(j,K) - 1 \). For each Input/Output-gate \( i \), and each \( l \) in the range \( 1 \leq l < 2k + 4n + 6 \), greedy all-switches strategy improvement will switch \( t_{i,l}^{1-j} \) to \( \chi_{m+1}^{B,K,j}(t_{i,l}^{1-j}) \) and \( d_i^{1-j} \) to \( \chi_{m+1}^{B,K,j}(d_i^{1-j}) \).

**Proof.** Much like the proof of Lemma J.3, this claim can be proved using essentially the same reasoning given as was given for Lemmas D.1, D.2, E.1, E.2, E.3, E.5, and E.4, because an Input/Output-gate behaves exactly like a NOT-gate.

In particular, note that we have defined \( \chi_{\text{Delay}(0,K)}^{B,K,0} = \chi_1^{B,K,1} \) and \( \chi_{\text{Delay}(1,K)}^{B,K,1} = \chi_0^{B,K+1,0} \), the gate gadgets in circuit \( 1-j \) continue to have well-defined strategies, so the \( d_i^{1-j} \) will continue to act like a NOT-gate between iterations 1 and 2.

The one point that we must pay attention to is that, in the transition between \( \chi_1^{B,K,j} \) and \( \chi_2^{B,K,j} \), the state \( y^{1-j} \) switches from \( r^{1-j} \) to \( r^j \). Note, however, that both \( h_{i,0}^j \) and \( p_i^j \) both switch to vertex that eventually leads to \( r^j \) at exactly the same time, so all paths that exit the gadget will switch from \( r^{1-j} \) to \( r^j \). Since almost all of the reasoning in the above lemmas is done relative to \( r^j \), the relative orders over the edge appeals cannot change.

The only arguments that must be changed are the ones that depend on Lemma B.8. Here, the fact that the priority \( P(5, i, 2k + 4n + 5, j, 0) \) is assigned to \( p_i^{1-j} \) is sufficient to ensure that \( \text{Val}^p(r^j) \subseteq \text{Val}^p(t_{i,l}^{d(C)}) \), so the deceleration lane will continue switching. On the other hand, since \( P(5, i, 2k + 4n + 5, j, 0) < P(7, 0, 0, 0, 0) \), this priority is not large enough to cause \( d_i^j \) to switch away from \( e_i^j \), if \( B_i = 1 \). \( \square \)
