Abstract. Quantum systems with a strangeness degree of freedom are very important as they provide an extra dimension, and hence a deeper insight into nuclear matter. Usually phenomenological potentials obtained through meson exchange theories are used in investigating these hypernuclear systems. In this paper potentials for lambda-nucleon interactions in the spin singlet and spin triplet states, constructed through fixed-angular momentum inversion based on Marchenko theory, are presented. Owing to experimental difficulties in obtaining a sufficient number of lambda-nucleon scattering events, theoretical phase shifts are used as input for the inversion. The constructed potential is energy-independent, making it more suitable for quantum-mechanical few-body calculations.

1. Introduction
The choice of a suitable baryon-baryon potential for use in simulations has been one of the preoccupations right at the heart of nuclear physics for much of its history. In particular, the last two or three decades have seen an increased effort towards understanding baryon-baryon interactions for systems with a strangeness degree of freedom. Much of the effort has been directed towards single and double strangeness systems. These potentials are important for many reasons. For example, they are used as input in simulations of hypernuclei. The glue-like role of hyperons within hypernuclei and the non-mesonic decay of hyperons in large-baryon number systems through the weak interaction are phenomena requiring further elucidation, that may only come from more reliable hyperon-nucleon potentials. These interactions also provide a deeper understanding of multistrangeness systems such as present at the core of a neutron star, whose equation of state depends on hyperon-nucleon and hyperon-hyperon potentials.

Meson-exchange theories have been the principal framework for developing most of the hyperon-nucleon and hyperon-hyperon potentials currently in use for few-body calculations. The most widely used meson-exchange potentials are the soft-core versions of the Nijmegen potentials [1], which were first formulated in [2]. A historical review of the development of the Nijmegen potentials is found in [3] and [4]. While most of these potentials do successfully address certain important issues such as the overbinding problem, they still suffer some inadequacies. The sensitivity of few-body calculations to the choice of potentials is symptomatic for these inadequacies, within the error limits of the few-body method used. Could these inadequacies stem from a much wider problem of nuclear physics using potentials constructed between
structureless hadrons, even at energy scales for which the quark degrees of freedom in Quantum Chromodynamics (QCD) represent the “correct” physics? Already, there has been considerable effort in building new potentials based on QCD. The Kioto-Niigata potential for all interactions between spin-1/2 octet baryons \((n, p, \Sigma^+, \Sigma^0, \Sigma^-, \Xi^-, \Xi^0\) and \(\Lambda)\) is one such development [5–7]. However, these quark-model potentials have not enjoyed as widespread use in few-body calculations as the meson-exchange potentials. A more systematic inclusion of QCD theories in nuclear physics may hold more for the future of nuclear physics, as QCD is the underlying theory of the strong interaction. The ambiguities of the currently used hypernuclear potentials make it necessary to investigate potentials obtained using a different theory.

In this paper we propose new potentials for the \(\Lambda N\) interaction in the spin singlet and triplet states, constructed not using QCD theories, but through quantum inverse scattering theory. The fixed-angular momentum approach has been used in solving this inverse scattering problem. Owing to its simplicity when compared to Gel’fand-Levitan inversion, the Marchenko inversion scheme is used. The rest of the paper is organised as follows: Section 2 provides a brief recapitulation of quantum inverse scattering at fixed angular momentum, Section 3 is devoted to \(\Lambda N\) scattering experiments and theoretical scattering data, while Sections 4 and 5 contain the results and conclusion, respectively.

2. The scattering matrix to potential inverse problem

2.1. Marchenko theory

Inversion may either be performed from experimental observables to the potential, or from the scattering matrix to the potential. The inversion from scattering matrix to potential may either be done at a fixed angular momentum \((\ell)\) or at a fixed energy \((k)\), or using a hybrid formalism for a given energy range and set of angular momenta. The normalisation \(\hbar^2 = 2\mu = 1\) is used. A detailed review on inverse scattering theory is found in the monograph by [8], while an up-to-date review on applications in nuclear physics may be found in [9]. Of interest in this paper is Marchenko inversion, one of the fixed-angular momentum formalisms. For a short-range potential \(V_\ell(r)\) with spherical symmetry the potential at each partial wave \(\ell\) is constructed by solving the following Fredholm integral equation for \(K_\ell(r, r')\):

\[
K_\ell(r, r') + A_\ell(r, r') + \int_r^\infty K_\ell(r, s)A_\ell(s, r')ds = 0 \tag{1}
\]

Here \(A_\ell(r, r')\) is a symmetric input kernel. This input kernel is constructed as in [10], taking into account any bound states:

\[
A_\ell(r, r') = \frac{1}{2\pi} \int_{-\infty}^\infty h_\ell^+(k, r)\left\{1 - S_\ell(k)\right\} h_\ell^+(k, r')dk + \sum_{i=1}^{n_b}\frac{1}{M_i} h_\ell^+(k_i, r)h_\ell^+(k_i, r') \tag{2}
\]

where \(S_\ell(k)\) is the scattering matrix, \(n_b\) is the number of physical bound states, if there are any, and \(h_\ell^+(k, r)\) are Riccati-Hankel functions. The \(M_i\) are normalisation constants for the bound-state wavefunctions. The unphysical bound states, also known as the Pauli forbidden states, which may arise are usually removed through supersymmetry. The functions \(h_\ell^+(k, r)\) are defined as follows:

\[
h_\ell^+(k, r) = i e^{i\pi\ell} \left(\frac{\pi kr}{2}\right)^{\frac{\ell}{2}} H^{(1)}_{\ell+\frac{1}{2}}(k, r) \tag{3}
\]
where $H_{n}^{(1)}(k, r)$ is a Hankel function of the first kind of order $n$. For the case of interest, $\ell = 0$, the Riccati-Hankel functions take the form

$$h_{0}^{+}(k, r) = i \left(\frac{\pi kr}{2}\right)^{1/2} H_{1/2}^{(1)}(k, r)$$

(4)

In inversion theory $K_{\ell}(r, r')$ arises as the kernel of a transformation from the solution of the radial Schrödinger equation for a free particle to any solution of the radial Schrödinger equation, for example the Jost solutions [11,12]. Furthermore, this output kernel, which has the property of strict upper triangularity ($K_{\ell}(r, r') = 0$, $r > r'$), satisfies a Goursat problem which is right at the heart of quantum inverse scattering [13–18]. The auxiliary condition of this Goursat problem on the characteristic curve $r = r'$ ensures that the derivative of the diagonal entries in the kernel provides the scattering potential i.e.

$$-2\frac{d}{dr} K_{\ell}(r, r) = V_{\ell}(r)$$

(5)

Therefore, solving the inverse problem of scattering matrix to potential can be understood in proper mathematical terms as reconstructing the auxiliary conditions of this Goursat problem.

Marchenko inversion theory has been used to construct particle-particle potentials, in particular nucleon-nucleon potentials [19–23]. [9] contains an extensive list of references for particle-cluster and cluster-cluster potentials that have been constructed through inversion theory, for example the neutron-alpha potential.

Here, we apply Marchenko inversion theory to construct $\Lambda N$ potentials. A motivating factor for such an attempt stems from the fact that the widely used models for the $\Lambda N$ potential disagree with experimental results in terms of single lambda binding energies ($B_\Lambda$) of ground state and excited states, even for low-baryon number hypernuclei.

2.2. Regularisation of linear system

Theory requires that $S_{\ell}(k)$, which is a complex-valued function, should be known for all energies or wavenumbers i.e. $k \in [0, \infty)$. However, the scattering matrix is obtained from the phase shift, which is itself derived from experimental observables: $S_{\ell}(k) = \exp(2i\delta_{\ell}(k))$, where $\delta_{\ell}(k)$ is the phase shift. The energy range of these experimental observables are limited by laboratory circumstances, thus limiting the energy range for which $S_{\ell}(k)$ is known. With such a scattering matrix, the inverse problem of computing the potential from the scattering matrix results in a linear system in which there are more degrees of freedom than there are constraints to restrict these degrees of freedom.

In order to solve this inverse problem, some form of regularisation is needed, so as to provide additional information. The most common approach, which is also the one that has been used in this paper, is to interpolate $S_{\ell}(k)$ using a rational function, and then extrapolating it to sufficiently high energies. Making use of the Bargmann rational-function representations of the Jost functions [8], the following interpolation, which explicitly shows the singularities of the Jost functions, is used:

$$S_{\ell}(k) = \prod_{n=1}^{N} \frac{k + \alpha_{n}^{\ell}}{k - \alpha_{n}^{\ell}} \frac{k - \beta_{n}^{\ell}}{k + \beta_{n}^{\ell}}$$

(6)

Here $\alpha_{n}^{\ell}$ are $N$ simple poles situated both in the upper-half and lower-half $k$ plane, while $\beta_{n}^{\ell}$ are $N$ simple poles situated only in the lower-half $k$ plane [24,25]. For uniformity, one may use the
same symbols to represent all the roots and singularities of the scattering matrix. In this case the parametrization takes the following form:

\[ S_\ell(k) = \prod_{n=1}^{M} \frac{k + \alpha_\ell^n}{k - \alpha_\ell^n}, \quad \text{where} \quad M = 2N \]  

This parametrisation ensures conservation of probability current (unitarity of \( S_\ell(k) \)). It also results in an exact solution to the Fredholm integral equation, as its kernel becomes degenerate; no quadrature is therefore needed [26]. [22] gives an outline of the procedure for transforming the integral equation into a linear system.

3. ΛN elastic scattering
There is very little data on ΛN scattering from experiments. This is because of the difficulty in using free hyperons as projectiles or targets in these experiments, owing to their very short lifetimes (about 10^{-10} s). When compared to free protons that do not decay, the extremely short lifetime of free hyperons poses enormous difficulties. Cross sections for the Λp elastic scattering reaction

\[ \Lambda + p \rightarrow \Lambda + p \]  

have been reported for laboratory-frame Λ momenta up to a few hundreds of GeV/c. Most of the Λp scattering data obtained have large error bars, and a low number of scattering events, insufficient to constraint the ΛN interaction. The use of such high-momentum Λ beams has significantly increased the Λ decay lengths from a few millimetres to several centimetres, thereby increasing the chances of scattering events in recent experiments. However, the higher the incident momenta, the greater the number of partial waves that must be accounted for; usually, the s-waves only suffice at low incident momenta. In an experimental set up Λn scattering is not as manageable as Λp scattering, due to the non-existence of free stable neutron targets. The lifetime of a free neutron is only approximately 881.5 s.

The link between quantum scattering theory and two of the observables that are usually measured in scattering experiments, differential cross section \( (d\sigma/d\Omega) \) and integrated cross section \( \sigma \), is established by the scattering amplitude, \( f_k(\theta) \). The scattering amplitude accounts for the distortion suffered by the incoming wave after scattering. In terms of partial wave analysis, the scattering amplitude may be written in the Faxen-Holtzmark formalism [27] as

\[ f_k(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} (2\ell + 1)(S_\ell(k) - 1)P_\ell(\cos \theta) \]  

where \( P_\ell \) is a Legendre polynomial at scattering angle \( \theta \). Solving the Radial Schrödinger Equation, one gets the phase shift, which is directly related to the scattering amplitude and cross sections. Using phase shift analysis, the contribution of each partial wave may be independently extracted. A poor phase shift analysis may therefore compromise the inversion procedure. This is an issue which is not of interest in this paper.

For our construction we have used as input theoretical \(^1S_0\) and \(^3S_1\) phase shifts computed by [28] for the NSC97f potential. Even after NN elastic scattering data became widely available, theoretical NN data continued playing an important role in our understanding of the NN force. It is hoped that this strategy will throw more light on the nature of baryon-baryon interactions in the single strangeness sector.
4. Results

The results are shown for the $s$-wave $\Lambda p$ (Figures 1(a) and 1(b)) and $\Lambda n$ (Figures 2(a) and 2(b)) potentials, both in the $S = 0$ and $S = 1$ states. The general features of a baryon-baryon interaction are present in these potentials, except for the $\Lambda n(^3S_1)$ potential where the short range repulsion is absent. The well-known result, that the $\Lambda N(^3S_1)$ potential is weaker than the $\Lambda N(^1S_0)$ potential, is also verified. However, an important feature of these potentials is that the strongest attraction occurs at a smaller radial distance than with most other lambda-nucleon potentials.

Figure 1: $\Lambda p$ potential in (a) $^1S_0$ state and (b) $^3S_1$ state.

![Graph](image2)

Figure 2: $\Lambda n$ potential in (a) $^1S_0$ state and (b) $^3S_1$ state.

Poor choices of $S_{\ell}(k)$ parametrisation have been known to result in unphysical oscillations in inversion potentials, even in cases where phase shifts from experiments are used [29]. These oscillations are absent in the results obtained here. However, the presence of a small repulsion barrier, which is quite negligible in the spin triplet states, may still be a pathology arising from the parametrisation. Since $\Lambda$ is a neutral elementary particle, this barrier could not possibly be a Coulomb repulsion. Further investigation is needed to clarify the effects of various $S_{\ell}(k)$ interpolations. This computational artefact is not expected to detract from the overall usefulness of our potential. This may be better appreciated in light of the inadequacies of the current potential models used in quantum-mechanical few-body calculations.
5. Conclusions
New spin singlet and spin triplet state potentials for the $\Lambda p$ and $\Lambda n$ interactions have been constructed for $\ell = 0$ through Marchenko theory, a quantum inverse scattering formalism. These potentials are energy-independent, a feature that makes them ideal for few-body calculations.
