We investigate how to experimentally detect a recently proposed measure to quantify macroscopic quantum superpositions [Phys. Rev. Lett. 106, 220401 (2011)], namely, “macroscopic quantumness” $I$. Schemes based on overlap measurements for harmonic oscillator states and for qubit states are extensively investigated. Effects of detection inefficiency and coarse-graining are analyzed in order to assess feasibility of the schemes.

I. INTRODUCTION

Macroscopic quantum states have provoked the imaginations of many physicists since the early days of quantum mechanics [1]. Creation and detection of macroscopic quantum superpositions are difficult but interesting tasks. Efforts towards such implementations have been made, for example, using atomic/molecular systems [2,3], superconducting circuits [4,5], and optical setups [6,8]. One very important issue in efforts to create and detect a macroscopic superposition is to have a measurable quantity that quantifies the degree of macroscopic quantumness of a given state. Since the initial attempt by Leggett [9], there have been various proposals and discussions of such measures [10–24]. In particular, a measure that quantifies the degree of macroscopic superposition for arbitrary harmonic oscillator systems, including mixed states, was proposed [18]. This measure, which we will call “macroscopic quantumness” $I$, can be straightforwardly calculated if the density matrix of a state under consideration is known. However, this is generally not the case, and given the difficulties in performing a quantum state tomography it would be useful to have an experimental method to measure directly the value of $I$. In this paper, we investigate several schemes to detect $I$ using overlap measurements and discuss their experimental feasibility.

This paper is organized as follows. In Sec. II we briefly review measure $I$ as a general quantifier of macroscopic quantum superpositions. We then discuss in Sec. III a general method based on an overlap measurement to observe $I$ experimentally, and explain two broad categories of overlap measurements. The next two sections, IV and V, describe each method in detail for harmonic oscillator (continuous variable) systems and two-level (qubit) systems. In Sec. VI, we investigate the effects of experimental imperfections including coarse-graining and detection inefficiency. A summary with some remarks is given in Sec. VII.

II. MACROSCOPIC QUANTUMNESS $I$

The original motivation behind the proposal of $I$ came from the high-frequency oscillations in the Wigner functions for the Schrödinger-cat-like states. The Wigner function that visualizes a quantum state in the phase space can be calculated from the characteristic function, which for a density operator $\rho$ is defined as

$$\chi(\xi) = \text{Tr} \left[ \rho e^{\xi \hat{a}^\dagger - \xi^* \hat{a}} \right],$$

where $\hat{a}$ and $\hat{a}^\dagger$ are the bosonic annihilation and creation operators, respectively. The Wigner function $W(x,y)$ is defined as the Fourier transform of the characteristic function [25],

$$W(x,y) = \frac{1}{\pi^2} \int \int d\xi_r d\xi_i \chi(\xi_r, \xi_i) e^{-2i(x\xi_r - y\xi_i)},$$

where the subscript $r$ ($i$) denotes the real (imaginary) part of $\xi$. The frequency of a Wigner-function component along the real (imaginary) axis is $\xi_r$ ($\xi_i$) and its complex amplitude for a specific frequency $\xi$ corresponds to $\chi(\xi)$.

As a typical example, let us consider a superposition of two coherent states (SCS) [6,20,29]

$$|\psi_{\text{SCS}}\rangle = N_+ (|\alpha\rangle + |-\alpha\rangle),$$

where the amplitude $\alpha$ is assumed to be real without loss of generality and $N_+$ is the normalization factor. In the phase space, its Wigner function displays interference fringes between two peaks at $\pm \alpha$ as shown in Fig. 1(a) for $\alpha = 2.3$. Suppose that someone could generate a “larger” superposition state by increasing the amplitude $\alpha$, while the generation process makes it partly lose interference between the two coherent states. Such a mixed state should be represented in a more general form as

$$\rho_{\text{SCS}} = N_\Gamma \left[ |\alpha\rangle\langle\alpha| + |-\alpha\rangle\langle-\alpha| + \Gamma (|\alpha\rangle\langle-\alpha| + |-\alpha\rangle\langle\alpha|) \right],$$

where $0 \leq |\Gamma| \leq 1$ and $N_\Gamma$ is the normalization factor. If $\Gamma = 1$, it becomes a pure SCSs whereas it is totally
mixed when $\Gamma = 0$. Figure 1(b) presents an example of a partially mixed state with $\Gamma = 0.46357$ and larger amplitude $\alpha = 4.96$. Now the problem is to find a measure of macroscopic quantumness that can account for the increase in “size” and decrease in “quantumness” during this process.

First, we note that the “frequency” of the fringes (how dense the fringes are) reflects the “effective size” of the superposition, i.e., how far the component states separate in phase space. Second, the “quantum coherence” (here we mean the degree of genuine superposition against its completely mixed version in terms of the “pointer basis” [30]) relates to the magnitude of the interference fringes. The point is thus how to quantify both the “frequency” and “magnitude” of interference fringes in the Wigner representation to quantify the “macroscopicness” and “quantumness” at the same time. One promising way is to take an integral $\int d^2\xi (\xi_2^2 + \xi_1^2) |\chi(\xi)|^2$. This integral indeed combines the required factors, “effective size” and the “degree of quantum coherence”, in a single measure. The formal definition of the measure $I_{\text{ho}}$ for an $M$-mode harmonic oscillator system [18] is only slightly different:

$$ I_{\text{ho}}(\rho) = \frac{1}{2\pi M} \int d^2\xi \left( \sum_{m=1}^M \left| \xi_m \right|^2 - 1 \right) |\chi(\xi_1, \xi_2, \ldots, \xi_M)|^2 $$

where $\int d^2\xi = \int d^2\xi_1 \int d^2\xi_2 \cdots \int d^2\xi_M$ and $-1$ has been inserted simply to make any coherent states or their product states (regardless of their amplitudes) a reference with $I_{\text{ho}} = 0$.

As discussed in Ref. [31], the factor $-1$ in Eq. (5) may be unnecessary as it causes $I$ to have negative values for some mixed states [31] [32]. If we remove the factor $-1$ from the definition (for example, take $\int d^2\xi (\xi_2^2 + \xi_1^2) |\chi(\xi)|^2$ as the definition for single-mode harmonic oscillator states), the measure will always be non-negative and become zero only for an extreme mixture $\sum_{n=0}^\infty |n\rangle\langle n|$ where $|n\rangle$ is a number state [31]. Since this change does not make an essential difference from the original version [5], we stick to the original definition in this paper. We also note that the measure $I$ is invariant under the displacement operation [18] because it simply shifts the Wigner function without changing its shape in the phase space. Therefore, for example, the class of states generated by applying the displacement operations on microscopic entanglement [33] [35] cannot have high values of $I$.

Returning to the example of SCSs, Fig. 1(a) corresponds to a superposition of two coherent states with a relatively small effective size but with the full quantum coherence, while Fig. 1(b) to the larger effective size with a partial coherence. Sensibly, the measure $I_{\text{ho}}$ gives the same value ($\approx 5.29$) for the two cases. The aforementioned definition of $I$ can be applied to arbitrary states in harmonic oscillator systems such as bosonic fields (quadrature variables of light) and mechanical states with motional degrees of freedoms.

There is also an alternative definition [18] that takes note of fast decoherence rates of macroscopic superpositions [30]. Taking the purity decay rate as a measure of a macroscopic superposition, a more general definition of $I$ is

$$ I(\rho) = \frac{-1}{2} \frac{d\mathcal{P}(\rho)}{d\tau}, $$

where $\mathcal{P}(\rho) = \text{Tr}(\rho^2)$ is the purity of state $\rho$ and $\tau = (\text{decay rate}) \times (\text{time})$ is the dimensionless time. It is straightforward to show that $I$ may also be represented as

$$ I(\rho) = -\text{Tr}[\rho \mathcal{L}(\rho)], $$

where $\mathcal{L}(\rho) = d\rho/d\tau$ is a Lindblad superoperator. Interestingly, this seemingly unrelated definition of $I$ is shown to be identical to the definition given in Eq. (5) [18], if one takes a well-known decoherence model:

$$ \mathcal{L}_{\text{ho}}(\rho) = \sum_{m=1}^M \left[ \hat{a}_m \rho \hat{a}_m^\dagger - \frac{1}{2} \rho \hat{a}_m^\dagger \hat{a}_m - \frac{1}{2} \hat{a}_m \hat{a}_m^\dagger \rho \right], $$

which describes the decay (photon loss) mechanism for optical fields [25] [36].

Following the definition (6), instead of harmonic oscillator systems, one may also consider the degree of macroscopic quantumness for qubit states (two-level systems spanned in a $2^{\otimes N}$ Hilbert space) such as spin-1/2 systems. Assuming that dephasing dominates over decay of multi-qubit systems, $\mathcal{L}(\rho)$ may be replaced with the dephasing model [37]

$$ \mathcal{L}_{\text{qubit}}(\rho) = \frac{1}{2} \sum_{m=1}^M \hat{\sigma}_{z,m} \rho \hat{\sigma}_{z,m} - \rho $$

and $I_{\text{ho}}(\rho) = -\text{Tr}[\rho \mathcal{L}_{\text{qubit}}(\rho)]$. In this paper, we consider how to measure the purity decay rate for both optical fields based on Eq. (5) and qubit systems based on Eq. (7). In what follows, we shall use notation $I(\rho)$ without the subscripts used above as far as its meaning is obvious in the context.
Fig. 2. Measurement scheme for determining the macroscopic quantumness $I$ for a density matrix $\rho_{in}$. The overlap is measured twice, with and without induced decoherence.

III. DETECTING MACROSCOPIC QUANTUMNESS $I$

A. General scheme using an overlap measurement and added decoherence

Being a nonlinear functional of $\rho$, experimental detection of $I$ seems to require a reconstruction of $\rho$, which becomes quickly intractable with increasing system size. There are, however, ways to measure nonlinear functionals of a density matrix experimentally. In particular, given two copies of $\rho$, it is possible to measure the purity of a quantum state $[38–47]$. This fact allows one to measure $I$ by simply noting that it can be written as the limit $\Delta \tau \to 0$ of

$$I_{\Delta \tau}(\rho) = \frac{\mathcal{P}(\rho(\Delta \tau)) - \mathcal{P}(\rho)}{2 \Delta \tau},$$

which is a measurable quantity, given a purity measurement scheme and ways to induce small decoherence. The situation is depicted in Fig. 2.

For optical fields, the decoherence caused by loss of photons can be induced simply by using a beam splitter with an appropriate reflectivity because of the equivalence between the two processes $[48, 49]$. The dotted boxes in Fig. 2 can thus be provided by beam splitters with an appropriate ratio determined by the decoherence time $\Delta \tau$. For the dephasing of qubit states, the method of decoherence may depend on how the qubits are implemented. For example, in the case of polarization systems, random phases can be artificially added using wave plates in a stochastic way to implement the decoherence effects.

B. Direct measurement and controlled-swap schemes for overlap measurements

Taking for granted that decoherence can be induced controllably via aforementioned methods, we discuss general schemes to measure the purity. Known approaches are based on a simple relationship for an overlap between two states, $\rho_a$ and $\rho_b$: $\text{Tr}[\mathcal{V}\rho_a \otimes \rho_b] = \text{Tr}[\rho]\rho_b$, where $\mathcal{V}$ is the swap operator defined by $\mathcal{V}|\psi_1\rangle|\psi_2\rangle = |\psi_2\rangle|\psi_1\rangle$. When $\rho_a = \rho_b = \rho$, the overlap yields the purity, so we discuss overlap measurements in order to keep the discussion more general. Broadly speaking, the overlap measurement approaches can be divided into two categories depicted in Fig. 3.

The first method, shown in Fig. 3(a) is to perform a direct measurement of the unitary operator $\mathcal{V}$ sol $[41, 43, 44, 50]$, comprised of an unitary operation that mixes two input states and subsequent detections. For the overlap between two qubits, this is equivalent to a measurement of the antisymmetric projector, which can be performed with a beam splitter and photodetectors for polarization qubits $[41]$. The case of two multi-qubit states has been studied by Alves and Jaksch $[43]$ in an optical lattice setting, where two internal states of the trapped cold atoms represent the qubit. The case of harmonic oscillator states has been first addressed by Pregnell $[44]$, where the author considers ‘decomposing’ the swap operator into a unitary transformation and a measurement. Very recently, Daley et al., rediscovered the method independently and generalized it to arbitrary multi-partite states $[50]$. The second method shown in Fig. 3(b) is to perform a controlled-swap (C-SWAP) operation, where the states are swapped only if the control qubit is in one of the computational basis states (for example, the vertical polarization state $|V\rangle$ for a single photon polarization qubit). The scheme is similar to the usual interferometer: the qubit goes through the Hadamard gate, a phase shifter, another Hadamard gate, followed by a (visibility) measurement, but different in that after the phase shift, controlled-swap operation is performed. The visibility then corresponds to the overlap between $\rho_a$ and $\rho_b$. $[38, 39, 42]$. Advantages of this method are 1) the detection is carried out only on the control qubit and 2) it is easily generalized to an arbitrary unitary operation other than the considered swap operation. A controlled-unitary operation can be performed with the help of pre-arranged entangled states and linear optics elements $[31]$. 

FIG. 2. Measurement scheme for determining the macroscopic quantumness $I$ for a density matrix $\rho_{in}$. The overlap is measured twice, with and without induced decoherence.

FIG. 3. Two schemes of an overlap measurement. (a) Direct measurement of the swap operator using an unitary mixing and detections. (b) Controlled-swap method where only a single detection is needed. In addition to the detector and the swap gate ($\mathcal{V}$), two Hadamard gates (H) and a phase shifter ($\phi$) are used.
IV. DIRECT MEASUREMENT SCHEMES

We first discuss direct measurement schemes in detail for \( n \)-partite states. When the system is comprised of \( n \) fundamental units (in this work we take a unit to be either a qubit or a harmonic oscillator), the swap operator for two \( n \)-partite states is simply

\[
\mathcal{V} = \mathcal{V}_1 \otimes \mathcal{V}_2 \otimes \mathcal{V}_3 \otimes \cdots \otimes \mathcal{V}_n \equiv \otimes_{k=1}^{n} \mathcal{V}_k ,
\]

where \( \mathcal{V}_k \) is a partial swap operator for the \( k \)-th system. A schematic illustration of direct measurement schemes for \( n \)-partite states is given in Fig. 4. One unit from the first system and a corresponding unit from the second goes through appropriate unitary interaction and detection processes. The unitary operation is of the beam-splitter type and together with detection is repeated throughout all units. In this section, we discuss these two processes in detail for harmonic oscillator states and qubit states.

A. Harmonic oscillator states

For the harmonic oscillator states, we give a brief review on the method of direct measurements discussed in \cite{44,50}. This method can be viewed either as diagonalizing the swap operator \( \mathcal{V} \) to decompose it into a unitary operation plus detection \cite{44} or mapping the symmetric and antisymmetric states into the subspaces of even and odd numbered quanta in one mode \cite{50}. In this method, the unitary operation corresponds to 50:50 beam splitting whereas the detection corresponds to the parity measurement performed on one of the beam splitter outputs. Basically, the unitary operation maps the antisymmetric part of the initial state into states with odd number of excitations in the upper output port and the symmetric parts into states with even number of excitations. Because the symmetric and antisymmetric states are eigenstates of the SWAP operator with eigenvalues 1 and \(-1\), respectively, the parity measurement yields the expectation value of the SWAP operator.

The unitary operation is generated by an interaction Hamiltonian of the form

\[
H = -iJ(a_{k,a}^{\dagger}a_{k,b} - a_{k,b}^{\dagger}a_{k,a}) ,
\]

where \( k \) is the site index and subscripts \( a, b \) denote copies of the density matrix. 50:50 beam splitting is obtained with \( Jt = \pi/4 \) and the parity measurement should be performed on the upper output port, i.e., the measurement operator is \((-1)^{n_k}\). The situation is depicted in Fig. 5 for a single site case. For \( n \)-partite states, the required detection is simply the parity of the total number of quanta in the upper modes of all sites, i.e., \((-1)^{\sum n_k}\), where \( n_k \) denotes the photon number in the upper mode at site \( k \).

The parity measurement in general requires a photon number resolving detector or a full quantum state tomography (for non-Gaussian states). The need of full tomography destroys the original intent of performing the purity measurement without full quantum state reconstruction (although the tomography is in a smaller subspace for multi-qubit states and therefore more manageable) and there is no photon number resolving detector to date. This means that, using current technology, it would be difficult to measure \( I \) directly via this method for interesting (high-photon number) macroscopic harmonic oscillator states. We note, however, that there are active ongoing researches in the development of photon number resolving detectors \cite{29,62}.

B. \( n \)-qubit states

The generalization of the decomposition method for harmonic oscillator states to multi-qubit states is straightforward and yields the following result, which, as far as we are aware, have not been given elsewhere. The beam-splitter-like unitary is generated by a Hamiltonian analogous to \cite{12}:

\[
H_{\text{BS}} = J (\hat{\sigma}_+ \otimes \hat{\sigma}_- + \hat{\sigma}_- \otimes \hat{\sigma}_+) ,
\]

performed for the duration \( Jt = \pi/4 \), acting on each pair of qubits. Operators \( \hat{\sigma}_\pm \) denote usual qubit raising and lowering operators. We note that the Hamiltonian is

\[
\rho_n \rightarrow (-1)^n \rho_n .
\]
proportional to $\tilde{\sigma}_x \otimes \tilde{\sigma}_x + \tilde{\sigma}_y \otimes \tilde{\sigma}_y$ and thus realizable in various spin systems. Due to the difference in commutation relationship between bosonic operators $a, a^\dagger$ and spin operators $\sigma_-, \sigma_+$, there is a slight change in the measurement part. Instead of the parity measurement on the first qubit, one has to measure the projection onto the state $|1\rangle$, i.e., the measurement operator is $(-1)^{|\langle \rho_1 | \rangle |}$. There exists an alternative method which is more suitable for single-photon polarization qubits with horizontally and vertically polarized single-photon states $|H\rangle$ and $|V\rangle$, for example. In order to see how this method works, note that the partial swap operator can be represented in the Bell-state basis as

$$V_k = P_{(k,+)} - P_{(k,-)}, \quad (14)$$

where $P_{(k,+)} = 1 - P_{(k,-)}$ and $P_{(k,-)} = \langle \zeta_- | \zeta_- \rangle_k$ with $|\zeta_-\rangle = (|H\rangle |V\rangle - |V\rangle |H\rangle)/\sqrt{2}$ denote the projectors onto the symmetric and antisymmetric subspaces of the $k$-th qubits, respectively. Consider a detection scheme that gives a ‘click’ at the $k$-th site when the qubits in the $k$-th site are in the antisymmetric state $|\zeta_-\rangle$. Then we can decompose the swap operator into

$$\text{Tr}|\rho_n \otimes \rho_d | = - (\text{The sum over probabilities of hearing clicks on an odd number of sites})$$

$$+ (\text{The sum over probabilities of all other click events})$$

$$= 1 - 2 \sum P_{\text{odd}}. \quad (15)$$

For single-photon polarization qubits, the detection of the antisymmetric portion can be simply carried out by first mixing two photons in a beam splitter and detecting the coincidence events \[56-58]. The same can be done for bosonic atoms, where the qubit is represented by two-species of atoms \[43]. There, the beam splitter interaction is provided by the usual tight-binding form.

**V. CONTROLLED-SWAP SCHEMES**

In general, the difficulty in implementing a C-SWAP operation is in finding the right type of nonlinear interaction. In this section, we summarize a previous proposal by Filip \[39\] for harmonic oscillators for completeness and provide a new scheme for single-photon polarization qubits based on a general scheme proposed by Zhou et al. \[51\]. We note that Lee et al.’s method \[17\] to implement a C-SWAP gate can also be applied for our purpose here.

**A. Harmonic oscillator states**

In Ref. \[39\], Filip noted that the C-SWAP gate on optical states can be written as

$$U_X = U_R^\dagger U_{CPS} U_R, \quad (16)$$

where $U_R = \exp \left( (\pi/4) \left( \hat{a}_0^\dagger \hat{a}_1 - \hat{a}_1^\dagger \hat{a}_0 \right) \right)$ is the usual 50:50 beam splitter unitary, $U_{CPS} = \exp \left( i \pi \hat{a}_1^\dagger \hat{a}_1 |V\rangle \langle V| \right)$ is a controlled phase shift operator, and $\hat{a}_0$ ($\hat{a}_1$) refers to the annihilation operator for mode 0 (1).

To see that $U_X$ is indeed the required operator, we first note that $U_R$ mixes the annihilation operators as $U_R^\dagger \hat{a}_0 U_R = (a_1 + a_0)/\sqrt{2}$ and $U_R^\dagger \hat{a}_1 U_R = (a_1 - a_0)/\sqrt{2}$ so that

$$U_X = \exp \left( \frac{i \pi}{2} \left( \hat{a}_0^\dagger (\hat{a}_1 - \hat{a}_0) + \hat{a}_1^\dagger (\hat{a}_1 - \hat{a}_0) \right) |V\rangle \langle V| \right). \quad (17)$$

From this expression it is easily seen that

$$U_X \hat{a}_0 |V\rangle \langle V| U_X^\dagger = \hat{a}_1 |V\rangle \langle V|,$$

$$U_X \hat{a}_1 |V\rangle \langle V| U_X^\dagger = \hat{a}_0 |V\rangle \langle V|,$$

$$U_X \hat{a}_0 |H\rangle \langle H| U_X^\dagger = \hat{a}_0 |H\rangle \langle H|,$$

$$U_X \hat{a}_1 |H\rangle \langle H| U_X^\dagger = \hat{a}_1 |H\rangle \langle H|,$$

completing the proof that the unitary operator $U_X$ is the sought-after C-SWAP operator.

The form of the controlled phase shift operator arises often in the discussion of quantum nondemolition measurements \[55\], which have been discussed in the settings of cavity quantum electrodynamics (QED) \[57, 58\], trapped ions \[59, 60\], and electromagnetically induced transparency (EIT) \[61, 62\] among others. The cavity QED scheme involves dispersive atom-field coupling, giving rise to an effective interaction of the form $\hat{a}^\dagger \hat{a} \tilde{\sigma}_+ \tilde{\sigma}_-$. The trapped ion version is based on a realization of the Hamiltonian $H = \lambda \hat{a}^\dagger \hat{a} (\tilde{\sigma}_+ + \tilde{\sigma}_-)$, which arises when the qubit is driven resonantly with a small Rabi frequency (smaller than the vibrational energy) \[63\]. The EIT version utilizes the cross-Kerr nonlinearity $\hat{a}^\dagger \hat{a} \hat{b}^\dagger \hat{b}$, i.e., the role of the qubit is now played by a single photon thus requiring large cross phase modulation \[61\].

**B. n-qubit states**

We now discuss a feasible scheme to detect macroscopic quantumness $I$ for multi-qubit states based on the linear
We then change the paths of the third and the fifth qubits becomes \(|\psi\rangle\) and \(|\phi\rangle\), however CP changes the paths of \(|\psi\rangle\) and \(|\phi\rangle\), conditionally interchange the original and auxiliary modes, perform swap on the auxiliary modes only, and interchange the paths conditionally once again. The main primitive used in this method is the controlled-path (CP) gate, which interchanges the paths of the two incoming photons only if the control qubit is in, say the state \(|V\rangle\).

To see how the scheme works, consider the initial state of the whole system, given the control qubit state \(|\psi\rangle\) = \(c_h |H\rangle + c_v |V\rangle\):

\[
c_h |H\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle + c_v |V\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle. \tag{19}
\]

The first two CP gates are applied as depicted in Fig. 6(a). As shown in Fig. 6(b), a CP gate can be implemented using two polarization beam splitters (PBSs), two C-NOT gates and a half-wave plate (HWP) [51]. If the control qubit \(|\psi\rangle\) is in \(|H\rangle\), CP does nothing. If it is in \(|V\rangle\), however, CP changes the paths of \(|\psi\rangle\) and \(|0\rangle\) (and \(|\phi\rangle\) and \(|0\rangle\)). Therefore, the state after the first two CP gates becomes

\[
c_h |H\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle + c_v |V\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle. \tag{20}
\]

We then change the paths of the third and the fifth qubits as shown in Fig. 6(a) to obtain

\[
c_h |H\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle + c_v |V\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle. \tag{21}
\]

The next two CP gates reverse the initial controlled-path change, so that the final state becomes

\[
c_h |H\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle + c_v |V\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle. \tag{22}
\]

Figure 6(c) presents an alternative way to construct an effective C-SWAP gate in the circuit. In place of the two CP gates after the path exchange, two beam splitters and four detectors are used. Furthermore, depending on the measurement outcomes of the detectors, a \(\pi\) phase shift may be performed on the target qubit. The state after the first CP gates and the path exchange is in Eq. (21). As states \(|\psi\rangle\) and \(|\phi\rangle\) are single photon states, there are four possibilities of detection after the two 50:50 beam splitters: \((D1, D3), (D1, D4), (D2, D3), (D2, D4)\) where the detector numbers are indicated in Fig. 6(c). The final state that gives rise to these possibilities are

\[
c_h |H\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle + c_v |V\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle, \tag{23}
\]

\[
-c_h |H\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle + c_v |V\rangle |\phi\rangle |0\rangle |0\rangle |\psi\rangle, \tag{24}
\]

\[
-c_h |H\rangle |0\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle + c_v |V\rangle |\phi\rangle |0\rangle |\psi\rangle |0\rangle, \tag{25}
\]

\[
c_h |H\rangle |0\rangle |\psi\rangle |0\rangle |\phi\rangle |0\rangle + c_v |V\rangle |0\rangle |\phi\rangle |0\rangle |\psi\rangle, \tag{26}
\]

in the same order. For the \((D1, D4)\) or \((D2, D3)\) case, a \(\pi\) phase shift should be performed on the target qubit. In this way, the same process for the overlap measurement
can be performed using only half the number of C-NOT gates compared to the scheme in Fig. 6(a). It is interesting to note that in the expense of the reduced number of C-NOT gates, exactly the same number of photodetectors have been inserted.

The method presented in Fig. 6(c) may be useful because an all-optical C-NOT gate requires a pre-arranged entangled state and is typically nondeterministic \[6\] \[65\]. The whole process described in this subsection can be extended to any two states with an arbitrary number of photons in each state. For example, an extension of the scheme in Fig. 6(a) with two states \(\rho_0\) and \(\rho_0\) is depicted in Fig. 6(d). In the same manner, the schemes in Fig. 6(c) can be extended to any two states with an arbitrary number of photons.

VI. EXPERIMENTAL IMPERFECTIONS

So far, we have discussed various overlap measurement schemes, any of which can be adopted to detect macroscopic quantumness \(I\) as detailed in the previous sections. In this section, we discuss the effects of two experimental imperfections: finite time resolution and imperfect detection efficiencies.

A. Effects of coarse-grained measurement

In an experiment, one is forced to use a finite value of \(\Delta \tau\) in Eq. (10), which leads to a certain amount of error in detecting \(I\). Below, we discuss through specific examples the effects of such coarse-grained implementations. The first example is SCSs \[6\] \[26\] \[29\] under the decoherence effect described by Eq. (8):

\[
\rho_{\text{scs}}(\tau) = N \left\{ |\alpha\rangle \langle \alpha| + |\lambda\rangle \langle \lambda| \right\} + \Gamma(\tau) \left( |\alpha\rangle \langle \alpha| - |\lambda\rangle \langle \lambda| \right), \tag{27}
\]

where \(t = \exp(-\tau/2), \Gamma(\tau) = \exp \left[ -2 \left( 1 - e^{-\tau} \right) \alpha^2 \right]\), and \(N\) is the normalization factor. Macroscopic quantumness is obtained as

\[
I(\alpha, \tau) = \langle \hat{n}(0) \rangle e^{-\tau} \sinh \left[ 2 \left( e^{-\tau} - 1 \right) \alpha^2 \right] / \sinh 2 \alpha^2, \tag{28}
\]

where \(\langle \hat{n}(0) \rangle \approx \alpha^2 \tanh \alpha^2\) denotes the average number of photons at \(\tau = 0\). This type of decoherence can be implemented using a beam splitter of reflectivity \(r = \sqrt{1 - e^{-\tau}}\). Note that for a pure SCS, the measure \(I\) equals the average photon number, i.e., \(I(\alpha, 0) = \langle \hat{n}(0) \rangle\).

Now, suppose that one intends to measure \(I\) for \(\rho_{\text{scs}}(\tau)\). This requires the purity of the state be measured twice at \(\tau\) and \(\tau + \Delta \tau\). As explained earlier, one may use two beam splitters of appropriate ratios to obtain \(\rho_{\text{scs}}(\tau)\) and

\[
\rho_{\text{scs}}(\tau + \Delta \tau). \text{ The purity of the SCS is}
\]

\[
\mathcal{P}(\rho_{\text{scs}}(\tau)) = \text{Tr}[\rho_{\text{scs}}^2(\tau)] = \tanh \alpha^2 \left[ 2 + 2 \cosh 2 \alpha^2 + \cosh \left[ 2 \left( e^{-\tau} - 1 \right) \alpha^2 \right] \right] \sinh 2 \alpha^2. \tag{29}
\]

Using Eqs. (10) and (29), we obtain and plot the measured quantity, \(I_{\Delta \tau}(\rho_{\text{scs}})\), as a function of \(\Delta \tau\) that can be measured via the proposed scheme. The values are obtained for SCSs under decoherence \(\rho_{\text{scs}}(\tau)\) with (a) \(\alpha = 1\) and (b) \(\alpha = 2\) as well as number states (c) and (d) under decoherence. The solid, dashed and dotted curves in each figure corresponds to \(\tau = 0, \tau = 0.1\) and \(\tau = 0.2\), respectively.

The next example we consider are photon number states (2) and (3). These states evolve under the decoherence as

\[
\rho_{\text{scs}}(\tau + \Delta \tau) = e^{-4\tau} |2\rangle \langle 2| + 2 e^{-\tau} G |1\rangle \langle 1| + G^2 |0\rangle \langle 0|, \tag{30}
\]

\[
\rho_{\text{scs}}(\tau + \Delta \tau) = e^{-3\tau} |3\rangle \langle 3| + 3 e^{-2\tau} G |2\rangle \langle 2| + 3 e^{-\tau} G^2 |1\rangle \langle 1| + G^3 |0\rangle \langle 0|, \tag{31}
\]

where \(G = 1 - e^{-\tau}\), and their purities are obtained as

\[
\mathcal{P}(\rho_{\text{scs}}(\tau)) = e^{-4\tau} + 4 e^{-2\tau} G^2 + G^4, \tag{32}
\]

\[
\mathcal{P}(\rho_{\text{scs}}(\tau)) = e^{-3\tau} + 9 e^{-2\tau} G^2 + 9 e^{-\tau} G^4 + G^6. \tag{33}
\]

The precise values of macroscopic quantumness for \(\rho_{\text{scs}}(\tau)\) are then

\[
I(\alpha, \tau) = 2 e^{-4\tau} - 4 e^{-3\tau} G + 4 e^{-2\tau} G^2 - 2 e^{-\tau} G^3, \tag{34}
\]

\[
I(\alpha, \tau) = 3 e^{-6\tau} - 9 e^{-5\tau} G + 18 e^{-4\tau} G^2 - 18 e^{-3\tau} G^3 + 9 e^{-2\tau} G^4 - 3 e^{-\tau} G^5. \tag{35}
\]
respectively. Figures 7(c) and 7(d) plot the coarse-grained measure, $\mathcal{I}_{\Delta \tau}$, as a function of $\Delta \tau$. We observe a similar behavior to that of the SCSs; a smaller value of $\Delta \tau$ is required for a larger number of photons in order to precisely represent $\tilde{I}$.

We conclude that given a small enough value of $\Delta \tau$, the coarse-grained measure $\mathcal{I}_{\Delta \tau}$ is not too different from $\mathcal{I}$, and one can safely propose $\mathcal{I}_{\Delta \tau}$ itself as the measure of macroscopic quantumness. The latter is then a coarse-grained version of $\mathcal{I}$:

$$\frac{1}{\Delta \tau} \int_0^{\Delta \tau} dt \mathcal{I}(\rho) = \mathcal{I}_{\Delta \tau}(\rho),$$

which follows from Eqs. (6) and (10).

### B. Effects of detection inefficiency

Another imperfection present in experiments is detection inefficiency, which we investigate here for both the direct and C-SWAP schemes.

#### 1. Direct measurement scheme

We first give our attention to harmonic oscillator states where experimentally demanding parity measurements are required. A single mode optical state $\rho_{in}$ (here, the subscription $in$ means 'input') can be expressed in the Glauber-Sudarshan representation

$$\rho_{in} = \int d^2 \alpha \; P_{in}(\alpha) |\alpha\rangle \langle \alpha|,$$

where $P(\alpha)$ is called the $P$ function. Using this representation, we can calculate how the input states evolve under the direct measurement scheme described in Sec. IV A (see Fig. 8). The state in the upper arm after a 50:50 beam splitter, $\rho_{mid}$, is

$$\rho_{mid} = \text{Tr} \left[ U_R \left( \rho_{in} \otimes \rho_{in} \right) U_R^\dagger \right] = \int d^2 \alpha \; d^2 \beta \; P_{in}(\alpha) P_{in}(\beta) \left| \frac{\alpha + \beta}{\sqrt{2}} \right\rangle \left\langle \frac{\alpha + \beta}{\sqrt{2}} \right|,$$

where the trace is taken over the field in the bottom arm. An imperfect detector with efficiency $\eta$ is modeled by placing a beam splitter with transmittance $\eta$ in front of a perfect detector. The beam splitter operator is $U_\eta = \exp \left[ \theta (\hat{a}^\dagger \eta \hat{a}^\dagger - \hat{a} \eta \hat{a}) \right]$ with transmittance $\eta = \cos^2 \theta$. When $U_\eta$ is applied to two coherent states, it yields $U_\eta |\alpha\rangle |\beta\rangle = |\sqrt{\eta} \alpha + \sqrt{1 - \eta} \beta\rangle | -\sqrt{1 - \eta} \alpha + \sqrt{\eta} \beta\rangle$. After passing through such a beam splitter, the state $\rho_{out}$ to be detected is

$$\rho_{out} = \text{Tr} \left[ U_\eta \left( \rho_{mid} \otimes |0\rangle \langle 0| \right) U_\eta^\dagger \right] = \int d^2 \alpha \; d^2 \beta \; P_{in}(\alpha) P_{in}(\beta) \left| \sqrt{\frac{\eta}{2}} (\alpha + \beta) \right\rangle \left\langle \sqrt{\frac{\eta}{2}} (\alpha + \beta) \right|,$$

which is obtained using $\sum_n (-1)^n \langle n | \rho_{out} | n \rangle = e^{-2\alpha^2}$.

Using this formula we will investigate the effects of detection inefficiency through the two examples used above. The first example is an SCS under the decoherence effect described by Eq. (27). Its measured purity with detection efficiency $\eta$ is

$$\tilde{\mathcal{P}} = \frac{1}{\tau} \int_0^\tau d\tau \tilde{I}(\alpha, \eta, \tau) = \frac{\eta}{2} \cot \frac{\eta}{2},$$

which yields the measured macroscopic quantumness

$$\tilde{I}(\alpha, \eta, \tau) = \frac{1}{\tau} \frac{d}{d\tau} \mathcal{P} = \alpha^2 \eta e^{-\tau} \sinh \left[ \frac{1}{2} (2 \eta e^{-\tau} - 1) \alpha^2 \right].$$
The measured macroscopic quannuntiness for the number states are:

\[ \tilde{I} \left( |2\rangle, \eta, \tau \right) = -2 \eta e^{-\tau} + 10 \eta^2 e^{-2\tau} - 18 \eta^3 e^{-3\tau} + 12 \eta^4 e^{-4\tau}, \] (43)

\[ \tilde{I} \left( |3\rangle, \eta, \tau \right) = -3 \eta e^{-\tau} + 24 \eta^2 e^{-2\tau} - 84 \eta^3 e^{-3\tau} + 156 \eta^4 e^{-4\tau} - 150 \eta^5 e^{-5\tau} + 60 \eta^6 e^{-6\tau}, \] (44)

which are plotted in Figs. 8(c) and 8(d). In both the cases, the measured values degrade as \( \eta \) decreases, while the number states are slightly more robust against the detection inefficiency.

We also briefly address inefficiency in the direct measurement schemes for qubits in Sec. 4.B. Consider the first method involving the spin-beam-splitter operation described by the Hamiltonian in Eq. (13) and a measurement of \((-1)^{I_1 I_2 I_3 I_0} I_1 I_2 I_3 I_0\). Assume that there are detectors that can distinguish between \( |0\rangle \) and \( |1\rangle \), whose inefficiency is such that these two states can be missed with equal probability. Then the detector inefficiency has no effect on the value of the measured observable, because it simply changes the total number of counts that has no effect on the measurement probabilities. Similarly, the effect of known detector inefficiency in the second method summarized by Eq. (15) can be taken into account in the calculation of the overlap from raw data. Here, the inefficiency in measuring the antisymmetric part of a subsystem in single site (involving two qubits) can be determined prior to the overlap measurement and subsequently used to counterbalance the bias due to the detector inefficiency.

2. Controlled-Swap Schemes

In the C-SWAP schemes, the control qubit (e.g., a polarized photon) may be lost before the detector because of the detection inefficiency. The result is a reduced number of counts, but since the detection efficiency is usually known, the correct number of counts can always be inferred, yielding straightforwardly the correct value of the purity. Furthermore, because there is only one qubit that needs to be detected at the final detector unlike in the direct measurement schemes, the effect of detection inefficiency can be easily corrected. This is an advantage of the C-SWAP schemes compared to the direct measurement schemes.

The correction of the inefficiency in detectors D1 to D4 in Fig. 9(c) is even easier, because the runs that do not have two detector clicks are simply discarded. On the other hand, if the fidelity of the CP gates is limited, it may cause the outcomes at D1-D4 to be biased and therefore degrade the accuracy of the final result. Such effects may be caused by the limited fidelity of the resource entangled states or mode mismatching at beam splitters.

VII. SUMMARY AND DISCUSSIONS

In this paper, we have briefly reviewed macroscopic quannuntiness \( I \) and described experimental methods to measure the quantity without requiring quantum state tomography, both for harmonic oscillator and qubit systems. Broadly, these methods can be sorted into two categories: Direct measurement schemes and C-SWAP schemes. After summarizing previously proposed schemes to achieve overlap measurements that can be applied to our purpose, we proposed a new C-SWAP scheme for single-photon polarization qubits. We have investigated effects of experimental limitations such as imperfect detection efficiencies and finite time resolutions.

Our method provides means to detect the macroscopic quannuntiness of various states such as SCSs [6, 26–29] in experiments without the need of quantum state tomography. For fully tomography, the number of measurement settings increases exponentially with the size of the state under consideration, whilst our scheme requires only two measurement settings, i.e., with and without induced decoherence. For qubit tomography, the number of measurement settings increases as \( \sim 4^n \) where \( n \) is the number of qubits [71, 72]. In contrast, only two settings are required for our scheme where simply the number of required detectors linearly increases as \( \sim n \) as shown in Fig. 4. A similar argument is applied to the case of harmonic oscillator states where many homodyne settings are necessary to perform a full tomography of an arbitrary state [73], while our method only requires two settings (again, with and without induced decoherence) with parity measurements.

Since the measure can be applied to mixed states [18], highly mixed states with nonclassical features [66–69] can also be analyzed. Furthermore, macroscopic superpositions and entanglement of spin systems [70] under dephasing effects may be simulated using the proposed optical setup to experimentally explore their behavior in terms of macroscopic quannuntiness.
