Acute bovine laminitis is a systemic disease with confined manifestations that affect the claws. It can cause serious economic losses to the dairy industry because cows with laminitis have reduced reproductive performance, decreased milk yield, high culling rates, and increased cost of veterinary intervention (6, 13). Equine laminitis is well-characterized, but the pathogenesis of acute bovine laminitis remains unclear. Recent studies have found that alimentary oligofructose (OF) induces acute bovine laminitis, leading to histological changes in the dermo-epidermal junction of the claws (6, 38).

Oxidative stress is defined as a change in the balance of cellular oxidation-reduction reactions, where there is an reactive oxygen species (ROS) are released excessively, and their removal is reduced due to inadequate antioxidant enzyme activity (22).

Increased activity of antioxidants may prevent cell damage caused by metabolic disorders (9, 41, 42). Laminitis is known to induce oxidative stress (28, 32), where under these oxidative conditions,
increased ROS causes hoof tissue dyskeratosis (40), cartilage degeneration, and chondrocyte apoptosis (17). Organisms have developed numerous defense mechanisms to prevent damage of the cellular structure caused by free radicals through the antioxidant defense systems (29).

Antioxidants are molecules that prevent or reduce free radical reactions to delay or prevent cellular damage (45). Antioxidants preserve cells from the harmful effects of free radicals. Free radicals are molecules that lack an unshared electron that is particularly active, and this electron can react rapidly with oxygen to form ROS. The body produces ROS endogenously as a result of normal cell activity, or as a response to exposure to free radicals in polluted air, cigarette smoke and ultraviolet radiations (UV) in sun rays. Cells control ROS levels through the antioxidative defense systems, while ROS activates antioxidant signaling between cells, leading to an increased antioxidative capacity, a process called oxidative stress (43).

Components of reactive oxygen species (ROS) are produced during physiological and metabolic functions causing harmful oxidative reactions under conditions of excessive production. Superoxide dismutase (SOD) is the first line of defense against ROS and is active in the detoxification of superoxide radicals (3, 11). Reduced glutathione (GSH) is the most important cellular antioxidant, which plays a major role in protecting cells against oxidative stress caused by ROS (1, 3, 34). Under normal conditions, catalase (CAT) is of no great importance to most cell types, but in the presence of oxidative stress it is the most adaptive antioxidant enzyme and plays an important role in cell defense against oxidative damage (14). Polyunsaturated fatty acids (PUFAs) in cell membranes are the primary targets of ROS. The resulting lipid peroxidation may cause damage of the cell structure and functions (15, 44). In addition, the decompositions of lipid hydroperoxides produces a wide variety of end-products, including malondialdehyde (MDA). One of the most frequently used ROS biomarkers, providing an indication of lipid peroxidation intensity, is MDA, which is a byproduct of lipid peroxidation (8, 10, 15, 30). The thiobarbituric acid (TBA) assay is the most common and easiest method used as an indicator of lipid peroxidation and free radical activity in biological samples. The assay is based on the reaction of two molecules of TBA with one of MDA (3, 30).

Changes in the activity of SOD, CAT, GSH, and MDA have not been reported in laminitis-induced dairy heifers. Therefore, we examined the level of oxidative stress and activities antioxidant enzymes during the first 72 h of animals developing induced acute bovine laminitis through OF overload. We hypothesized that oxidative stress caused by acute laminitis changes antioxidant enzyme activity levels in dairy heifers.

**Material and methods**

**Animals.** Twelve clinically healthy non-pregnant Chinese Holstein heifers with normal locomotion, without a history of serious claw lesions, aged between 18 to 26 months (20.67 ± 3.01 mo), weighing 335 to 403 kg (379.71 ± 19.87 kg), and with BCS ranging from 2.7 to 3.3 were selected. Before the commencement of the experiment, heifers were acclimatized for 30 days to assure free access to feed grass hay and adequate drinking water. Three days before the experiment, the jugular vein was catheterized.

**Experimental design and treatments.** Twelve heifers were allocated into two groups of six individuals: an OF-treated group and a control group. According to (6) the OF-treated heifers (n = 6) received 17 g/kg BW of oligofructose (Bailong Bio-Tech Company, Jinan, China) dissolved in 2 L/100 kg BW of tap water, whereas the control heifers (n = 6) received 2 L/100 kg BW of tap water at 0 h. Three days (72 h) before the high oral dose of oligofructose, a 5% dose of oligofructose was administered daily. During the pre-experimental period, heifers were trained to have their front feet lifted and examined, and to be directed by hand to walk and trot. During the experiment, all heifers were housed in a tie-stall on a concrete floor bedded with wood flakes to a depth of 2-4 cm and were fed grass hay ad libitum. After 72 hours of OF-overload, heifers were euthanized.

For animal welfare, supportive therapy was given as Ringer lactate (Peace Veterinary Medicine, Harbin China; 15 mL/kg BW) and sodium bicarbonate (Peace Veterinary Medicine, Harbin China; 84 g/L; 1.5 mL/kg of BW) at 18 and 24 h after oligofructose overload and calcium borogluconate (Peace Veterinary Medicine, Harbin China; 14 mL of Ca/mL; 1 mL/kg of BW) at 18 h.

The experiment was carried out following the animal ethical standards (animal ethics approval SRM-13) established by the College of Veterinary Medicine, Northeast Agricultural University in Harbin, Republic of China.

**Locomotion scoring and histopathological examination.** Locomotion scoring was assessed according to the method described by (39) as shown in Table 1. Histopathological examination of claw was carried out according to (7). The purpose of the locomotion scoring and histopathological examination were to provide unbiased confirmation or disproof of the development of the laminitis after OF overload.

**Blood sampling.** From selected control and OF-treated heifers, 5 ml blood

| Score | Description | Assessment criteria |
|-------|-------------|---------------------|
| 1     | Normal      | The heifer stands and walk with level-back posture. Its gait is normal. |
| 2     | Mildly lame | The heifer stands with level-back posture while walking develops an arched back-posture. Its gait remains normal. |
| 3     | Moderately lame | An arched-back posture is evident both while standing and walking. The heifer’s gait is best described as short striding with 1 or more limbs/feet. |
| 4     | Lame        | An arched-back posture is always evident and gait is best described as 1 deliberate step at a time. The heifer favors 1 or more limbs/feet. |
| 5     | Severely lame | The heifer additionally shows an inability or extreme reluctance to bear weight on 1 or more of its limbs/feet. |
samples were collected from jugular vein by puncture. Blood samples were centrifuged at 5000 r/min for 10 minutes to separate serum from plasma. The separated sera were used to determine the activity levels of superoxide dismutase (SOD), reduced glutathione (GSH), catalase (CAT) levels, and malondialdehyde (MDA).

Determination of SOD activity. SOD detection Microplate test Kit (cat no. A001-3 WST-1) from Nanjing Jiancheng Bioengineering Institute (Nanjing, People’s Republic of China) was used to evaluate total SOD activity. The assay was performed following the manufacturer’s instructions. SOD increases the dismutation of toxic superoxides that are generated by ROS to oxygen and hydrogen peroxide. To measure SOD activity, xanthine oxidase (XOD) and xanthine were combined to produce superoxide radicals that were mixed with water-soluble tetrazolium-1 (WST-1) to form a red water-soluble tetrazolium-1 formazan dye. SOD activity was measured by the degree of inhibition during this reaction. One unit of SOD activity was defined as 50 percent inhibition of WST-1 rate under assay conditions. A standard curve of SOD activity was generated 450 nm and expressed as unit micro per milliliter (U/mL).

Determination of reduced GSH activity. GSH detection assay kit (cat no. A006-2) from Nanjing Jiancheng Bioengineering Institute (Nanjing, People’s Republic of China) was used to test reduced GSH activity following the manufacturer’s instructions. In this reaction, GSH reacts with dithiodinitrobenzoic acid (DTNB) to form a yellow compound. Glutathione stabilizes enzymes containing a thiol group and prevents oxidative damage to hemoglobin and other cofactors. GSH is a low molecular scavenger that can scavenge O2 and H2. The content of reduced glutathione was determined quantitatively by colorimetry at 405 nm wavelengths. Using a standard OD curve, the reduced GSH activity was expressed as micro per milliliter (U/mL).

Determination of SOD inhibition ratio % = 
\[ \frac{(OD_{\text{control}} - OD_{\text{control blank}}) - (OD_{\text{sample}} - OD_{\text{sample blank}})}{OD_{\text{control}} - OD_{\text{control blank}}} \times 100\% \]

Serum SOD activity (U/mL) = 
\[ \frac{\text{Serum SOD inhibition ratio}}{50\%} \times \text{reaction system 0.24 dilution multiple 0.02} \]

Determination of reduced GSH activity. GSH detection assay kit (cat no. A003-1 TBA) from Nanjing Jiancheng Bioengineering Institute (Nanjing, People’s Republic of China) was used to evaluate MDA activity following the manufacturer’s instructions. The reaction of fatty acids with free radicals results in malondialdehyde, which is the final product of lipid peroxidation. The level of malondialdehyde can be evaluated with thiobarbituric acid, which can be measured colorimetrically. Using the blood serum sample, 200 ml was mixed with 800 ml phosphate buffer, 25 ml BHT solution, and 500 ml of 30% TCA. The tubes were boiled 90°C for 40 min. The tubes were agitated using a vortex and incubated on ice for 2 h for cooling. Next, the tubes were centrifuged at 3500 rpm for 10 min, and 1 ml supernatant was collected. The supernatant was mixed with 250 ml of TBA and 75 ml of EDTA, mixed using a vortex, and placed in a hot water bath for 15 min. Samples were moved to room temperature and absorbance was read in UV/V as spectrophotometer F4500 (Hitachi, Japan) at 532 nm. Using a standard OD curve, MDA activity was expressed as nano-mole per milliliter (nmol/mL).

Serum MDA activity (nmol/mL) = 
\[ \frac{OD_{\text{sample}} - OD_{\text{blank}}}{OD_{\text{standard}} - OD_{\text{blank}}} \times 10 \]

Statistical analysis. Data were analyzed by repeated-measures two way ANOVA and Bonferroni’s multiple comparisons test with a significance level of 5% using Graph pad Prism (Version 7.04, Graph Pad Software Inc., San Diego, CA). All data are presented as means ± standard error. Comparisons were considered to be statistically significant when p ≤ 0.05.

Results and discussion

Clinical signs. All the OF-treated heifers showed clinical signs of distinct acute ruminal and systemic acidosis symptoms, including increased heart rate, anorexia, depression, in-appetence, watery diarrhea, and transient fever. Control heifers showed no signs of systemic disease. During locomotion assessment, the clinical signs of laminitis were initially observed at 24 h after OF overload and found continuous increase up to 48 h at which we found locomotion score 2-3. The maximum locomotion score 3-5 was observed from 60 h which confirmed the acute laminitis in Chinese dairy heifers. These locomotion score were constant between 60 h to 72 h and we did not find any significant change. Therefore, the animals were then euthanized for further experimental requirements. These results are in line with (6) who found acute laminitis at 60-120 h of OF induction, while in our study the laminitis was observed maximum at 48 h. These early signs of acute laminitis can be correlated with animal breed, physical health, environmental condition and dose.
of oligofructose overload. Control heifers showed no change in locomotion score during the experiments. Histopathological examination of claw biopsy was carried out and preliminary results are presented in Fig. 1 and 2. In summary, clear differences were observed between the lamellar regions of OF treated and control heifers. These results are in line with (7) who confirmed the acute laminitis in heifers after OF overload by histopathological examination.

**Superoxide dismutase (SOD).** Serum SOD activity of the control and OF-treated heifers with acute laminitis are listed in Fig. 3. We found a significant reduction in SOD activity in OF-treated dairy heifers compared to the control group \((p < 0.01)\). SOD level was significantly lower \((p < 0.05)\) at 18 h compared to the control group, and there was a significant reduction in SOD levels \((p < 0.01)\) from 24 h to 72 h in OF-treated heifers. These results highlight that oxidative stress is involved in the pathogenesis of acute laminitis in dairy heifers.

**Reduced glutathione (GSH) activity.** A serum GSH levels of the control and OF-treated heifers are listed in Fig. 4. GSH level were similar for the OF-treated and control heifers \((p > 0.05)\).

**Catalase (CAT).** Serum CAT levels of the control and OF-treated heifers are listed in Fig. 5. CAT levels
Lipid peroxidation. A serum MDA activity of the control and OF-treated heifers with acute laminitis are listed in Fig. 6. MDA is a marker of oxidative stress, and we found significantly higher MDA levels (p < 0.01) in OF-treated heifers compared with the control group. The mean MDA levels were significantly higher (p < 0.05) at 12 h-18 h compared to the control group, and significantly higher (p < 0.01) from 24 h to 72 h in OF-treated heifers. Therefore oxidative stress is likely involved in the etiopathogenesis of acute laminitis, and deficient levels of antioxidants (enzymatic and non-enzymatic) may be correlated to oxidative stress status in ill heifers. When MDA enzyme activity was examined, the relationship between OF-treated group and control groups were statistically significant (p < 0.05).

The increased production of excessive free radicals caused by the animal’s interaction with various stress-inducing factors and the failure of the antioxidant defense system to remove these free radicals leads to oxidative stress (4, 47). Oxidative stress plays an important role in the pathogenesis of various diseases, such as respiratory, joint and foot diseases, sepsis, mastitis, acidosis, ketosis, enteritis and endoparasitic diseases in livestock (5, 24, 37).

A previous study (16) described a number of protection mechanisms against ROS in animals. Antioxidant enzymes include SOD, which catalyzes the breakdown of superoxide radicals to water and hydrogen peroxide, and CAT, which catalyzes the dismutation of hydrogen peroxide to water and oxygen. An important co-factor and antioxidant for various antioxidant enzymes is GSH, which is a tri-peptide thiol (20). We found significant changes in SOD levels, but not in CAT activity in heifers with laminitis. This may be because SOD is the central defense mechanism against ROS, and is involved in detoxification of superoxide radicals (12). The hydrogen peroxide that is generated from the reaction that SOD catalyses is then converted to water by CAT. It may be that the oxidative effects of laminitis are not extensive enough to affect CAT. SOD levels decrease in heifers with lameness (49), and in dairy heifers that have foot-and-mouth disease (19, 26).

An indicator of oxidative stress in cells is lipid peroxidation. Polysaturated fatty acids produce lipid peroxides that are unstable that are then disintegrated to MDA. The quantification of MDA is a proxy for lipid peroxidation (35). MDA is one of the main biochemical markers used to determine the degree of cellular damage in tissues (29, 33). MDA levels were significantly higher (p < 0.01) in heifers with lameness (49). Previous studies have found that MDA increases calves with inflammatory diseases, such as arthritis and omphalitis (2, 46), in the dairy cows with foot-and-mouth disease (19, 26) dogs with renal diseases (18) and sheep infected with Dicrocoelium dendriticum (35). Superoxide radical and hydrogen peroxide also accumulate as a result of brain injury (21).

In the present study, MDA levels were significantly higher in OF-treated heifers, highlighting that laminitis increases the presence of lipid peroxidation products. Polysaturated fatty acids are the principal targets of oxygen radicals, and disruption of fatty acids can lead to disorganization of cell structure (31).

The increased serum MDA level in lame heifers further verified that acute laminitis in dairy heifers caused oxidative stress. Significantly decreased levels of SOD observed in heifers with laminitis also provide support that oxidative impairment is a likely part of the pathogenesis of acute laminitis in heifers.

CAT and GSH are important antioxidants that inhibit free radicals (27), catalyzing reactions that reduce lipid peroxides and hydrogen in cells (48). GSH is a non-enzymatic antioxidant that defends the body against...
oxidative stress, and is involved in inactivation of free radicals (25).

CAT levels showed a non-significant decrease (p > 0.05) in OF-treated heifers compared to the control group. This nonsignificant decrease in the serum CAT levels may be interpreted as the excessive usage of CAT activity as a result of hoof leaf inflammation. A previous study also found non-significant differences in CAT activity in heifers with lameness (49).

Moreover, we found that serum GSH levels showed a non-significant decrease (p > 0.05) in the OF-treated group compared to the control group. This is consistent with a previous study that showed that GSH activity does not change in heifers with lameness (49).

ROS include superoxide radicals, hydrogen peroxide and hydroxyl radical. ROS affect the normal function of biomolecules such as proteins, nucleic acids, and cell membrane phospholipids. Free radicals are produced through the stepwise reduction of molecular oxygen (36). Normal cellular function does produce free radicals; however, excessive production and insufficient elimination of free radicals can lead to irreversible damages to the cell (23).

In conclusion, we found a relationship between acute laminitis and oxidative stress and found that SOD, GSH, CAT, and MDA levels may play a role in the etiopathogenesis of acute laminitis in dairy heifers. However, more research is needed to describe these responses and to develop strategies to control acute laminitis in heifers.
