Abstract

Large-scale language models such as ELMo and BERT have pushed the horizon of what is possible in semantic role labeling (SRL), solving the out-of-vocabulary problem and enabling end-to-end systems, but they have also introduced significant biases. We evaluate three SRL parsers on very simple transitive sentences with verbs usually associated with animate subjects and objects, such as Mary babysat Tom: a state-of-the-art parser based on BERT, an older parser based on GloVe, and an even older parser from before the days of word embeddings. When arguments are word forms predominantly used as person names, aligning with common sense expectations of animacy, the BERT-based parser is unsurprisingly superior; yet, with abstract or random nouns, the opposite picture emerges. We refer to this as common sense bias and present a challenge dataset for evaluating the extent to which parsers are sensitive to such a bias. Our code and challenge dataset are available here: github.com/coastalcph/comte

1 Introduction

Semantic role labeling (SRL) refers to a shallow semantic dependency parsing that returns predicate-argument structures for input sentences; see Figure 1. Modern-day SRL systems, like most other NLP technologies, rely heavily on large-scale language models. Such language models are extremely useful for generalizing to out-of-vocabulary items, making subtle syntactic distinctions, and for capturing a range of lexical ambiguities; but they also introduce notable biases.

Previous work has shown that SRL systems exhibit demographic biases (Zhao et al., 2017); we focus on a form of belief bias (Sternberg and Leighton, 2004), which we will refer to as common sense bias, reflecting how language models encode conventional associations, which in many ways are indistinguishable from common sense (Trinh and Le, 2019). While demographic biases can lead to discrimination against under-represented demographics, belief biases can lead to discrimination against rare events; or, more precisely, lead SRL systems to err on sentences that express unlikely states of affairs. This is what belief biases refer to in cognitive science (Sternberg and Leighton, 2004): human preferences for conclusions that align with values, beliefs, and prior knowledge. Belief biases in models can, like demographic biases, exacerbate societal challenges, e.g., anomaly detection, and also correlate with demographics, since groups differ in how much they engage with counterfactual and fictitious contents.

We compare the errors of a modern, competitive SRL system (Shi and Lin, 2019), based on BERT (Devlin et al., 2019), and show how it, unlike earlier SRL systems, suffers from common sense bias: When confronted with sentences that, when read literally, express unlikely states of affairs, it can ignore obvious cues and produce false predicate-argument structures even for very simple sentences. The sentence in Figure 1, for example, can be understood as expressing that the abstract concept of Memory babysat the abstract concept of Reasoning. The literal reading represents an unlikely state
of affairs, since abstract concepts generally do not have the capacity of babysitting. Obviously, this does not prevent language users from uttering the sentence, and it is, for most of us, not hard to make sense of it: The sentence, for example, could mean something like memory assists reasoning. Many similar sentences can be found in the wild, e.g., the US babysits Israel (from cnn.com) or Love bodyslams you (from quizlet.com). Other sentences express unlikely states of affairs, not because of linguistic creativity, but because they refer to possible worlds, not ours, for scientific, literary, political or other reasons. We believe it is critical that SRL parsers should be robust to such variation, but our experiments show that while SRL performance numbers have gone up dramatically in recent years, parsers seem to have become more sensitive to it.

2 Semantic Role Labeling Systems

Björkelund et al. (2009) combine three logistic regression classifiers with beam search and a global reranker: the first classifier identifies predicates, the second their arguments, and the third labels the semantic dependencies between predicates and their arguments. The system relies on a POS tagger and a syntactic dependency parser to generate features for the classifiers. This system had the second-best performance in the CoNLL 2009 Shared Task. Stanovsky et al. (2018) rely on a standard recurrent architecture. They use GloVe embeddings (Pennington et al., 2014), in conjunction with embeddings from a POS tagger, and stack bidirectional LSTM layers (Hochreiter and Schmidhuber, 1997) on top of the embedding layer. The representation at each time-step is passed to a classifier, which directly predicts the output label for that time-step. Unlike Björkelund et al. (2009), they do not rely on search, but reduce SRL to two-stage sequence labeling, both stages pretrained with BERT-large (Devlin et al., 2019); first identifying predicates, then arguments, while conditioning on the predicates.

3 Coarse-Grained Error Analysis

In our error analysis, we focus on simple three-word sentences that consist of a noun, a transitive verb, and a noun. The transitive verbs are handpicked to exhibit strong preferences for animate subjects and objects, low ambiguity, and predom-
where we can safely assume a

Table 2: Error rates and most frequent error types for common verbs in their present and past tense forms, in simple SOV constructions, e.g., *John calls Mary*. All numbers are for Shi and Lin (2019). Bold-faced error types most frequent (of the four presented here). The verbs bodyslams and babysits are used in our experiments, because (a) they have strong selectional restrictions for animate subjects and objects, (b) they predominantly realize $A_0$ and $A_1$ as subjects and objects (unlike *fails* and *calls*), and (c) while all English verbs tend to have noun readings, the verb readings are far more frequent (unlike for *trips* and *tips*).

| Verb       | Error | $A_0V_A$ | $A_1V_A$ | Syntax | Expl |
|------------|-------|----------|----------|--------|------|
| fails      | 0.898 | 0.006    | 0.758    | 0.009  | Syntax |
| calls      | 0.528 | 0.467    | 0.020    | 0.020  | POS  |
| trips      | 0.356 | 0.007    | 0.000    | 0.128  | POS  |
| tips       | 0.875 | 0.010    | 0.010    | 0.687  | POS  |
| bodyslams  | 0.373 | 0.065    | 0.052    | 0.034  |      |
| babysits   | 0.212 | 0.048    | 0.072    | 0.035  | ?    |

Table 2: Error rates and most frequent error types for common verbs in their present and past tense forms, in simple SOV constructions, e.g., *John calls Mary*. All numbers are for Shi and Lin (2019). Bold-faced error types most frequent (of the four presented here). The verbs bodyslams and babysits are used in our experiments, because (a) they have strong selectional restrictions for animate subjects and objects, (b) they predominantly realize $A_0$ and $A_1$ as subjects and objects (unlike *fails* and *calls*), and (c) while all English verbs tend to have noun readings, the verb readings are far more frequent (unlike for *trips* and *tips*).

Table 3: Main results: Error rates of three SRL systems across transitive sentences with person names in subject and object positions, versus country names, abstract nouns, (randomly chosen) plural common nouns, or random strings in those positions.

| Error          | Björkelund et al. (2009) | Stanovsky et al. (2018) | Shi and Lin (2019) |
|----------------|--------------------------|--------------------------|--------------------|
| names          | 0.158                    | **0.341**                | 0.077              |
| countries      | 0.183                    | **0.505**                | 0.030              |
| abstract       | 0.174                    | **0.353**                | 0.133              |
| random-nouns   | 0.188                    | **0.287**                | **0.310**          |
| random-strings | **0.997**                | 0.172                    | 0.313              |

Table 4: Simple sentences on which Stanovsky et al. (2018) and Shi and Lin (2019) both err. Björkelund et al. (2009), in contrast, assigns correct parses to all of these. Try yourself: barbar.cs.lth.se:8081/

performance drops considerably below the performance label with names or countries, when using abstract nouns, randomly sampled nouns, or simply random strings, as arguments, this suggests a common sense bias, seen very strongly with Shi and Lin (2019). Björkelund et al. (2009), in contrast, exhibits near-uniform performance across the different sets of arguments. Since the parser has no strategy to deal with out-of-vocabulary items, it exhibits worse performance on random strings. Stanovsky et al. (2018), surprisingly, seems extremely sensitive to country name arguments, and performance oddly improves with random strings arguments. Since these are out-of-vocabulary, the parser probably drops back to a default strategy. Notably, Shi and Lin (2019) does well on country names, there are plenty of examples that Stanovsky et al. (2018) and Shi and Lin (2019) get wrong, but that Björkelund et al. (2009) get right; see Table 4 for examples.

Table 2: Error rates and most frequent error types for common verbs in their present and past tense forms, in simple SOV constructions, e.g., *John calls Mary*. Comparison with Dependency Parser Errors
While only one of the parsers (Björkelund et al., 2009) relies on input features from a syntactic parser, it is tempting to think that, in line with previous error analyses of SRL systems (He et al., 2017; Strubell et al., 2018), the error distribution can be explained by syntactic ambiguities and resulting syntactic errors. This, perhaps unsurprisingly, turns out to reliably explain the error distribution observed with Björkelund et al. (2009). See Figure 3 for the syntactic parse on Memory babysits Reasoning, on which the log-linear parser fails to deliver any SRL analysis, interpreting the three-word sentence as a nominal compound. For the neural parsers, there is no correlation, however. We ran a syntactic parser (Dozat et al., 2017) on our three-word sentences and correlated errors across lemmata. We observed a small, but negative correlation between error rates.

4 Fine-Grained Error Analysis

Multitude of Errors Our first observation is that across all verb lemmata, the parser in Shi and Lin (2019) produces many different output trees, depending on the argument word forms. For some lemmata, the error distribution is near-uniform across 15-20 outputs. It is well-established in SRL that infrequent contexts lead to low confidence (Chen et al., 2011), explaining why common sense bias leads to a multitude of errors.

Morphosyntactic Ambiguity While parsing errors do not correlate with errors of Shi and Lin (2019) (§3), the SRL system seems to be sensitive to part-of-speech ambiguity. It errs, for example, on Insomnia trips jaywalking, but not on Insomnia tripped jaywalking, presumably because trips is (on its own) ambiguous. Sensitivity to such ambiguities disappears when aligning with common sense: The parser does not err on Mary trips John or Mary likes jaywalking. The same ambiguity leads to error in London trips John, but not in London tripped John. With the even more frequent surname of Washington, the effect disappears, and Shi and Lin (2019) get both verb forms right.

5 COMTE: A Test of Common Sense Bias

Our challenge dataset consists of 1,000 simple, three-word sentences with the same gold analysis: the second word is the predicate, the first word its $A_0$, the last word its $A_1$. The predicates are sampled at random from a list of six carefully selected verbs (see §3) that select for animate subjects and objects and consistently prefer these to be $A_0$ and $A_1$. As before, we combine the verbs with names, countries, abstract nouns, plural common nouns, and random strings. The sentences were simply the first 1,000 sentences that we sampled this way, with 200 sentences in each category (names, countries, etc.) – and which satisfied a simple criterion: Neither Shi and Lin (2019) nor (Stanovsky et al., 2018) would get it right. COMTE, in other words, consists of 1,000 trivial sentences that two competitive SRL parsers failed to parse correctly.

What can COMTE be used for? Obviously, it can not be used to fine-tune parsers on, for example. It would take only a few examples to learn what is going on in the data, and training would likely lead to over-fitting. COMTE can also not be used to derive parsing performance figures that tell us much about the performance of parsers in the wild. The 1,000 sentences should, in our view, be thought of as a single probe into the degree to which a parser is sensitive to common sense bias. A parser should rarely err on the examples in the challenge dataset: They are all trivially simple, and while some argument words can be ambiguous, the verbs so strongly select for simple $A_0VA_1$ frames that parsers should unambiguously prefer this reading. If they don’t, this is a sign they struggle with simple transitive sentences, like Stanovsky et al. (2018), or that they are prone to common sense bias, like Shi and Lin (2019). In order to quantify the degree to which the effect can be attributed to common sense bias, performance with names can be used as a baseline: If performance is much better for names than for some of the other categories, like with Shi and Lin (2019), this is an indicator of common sense bias.

Our dataset differs from previous challenge datasets for mixed language (Pal and Sharma, 2019), chat (Rachman et al., 2018), etc., in being synthetic.

---

This is orthogonal to the ambiguity of jaywalking; see Padó et al. (2008) for the analysis of nominal predicates.
