Abstract. Results of a careful analysis of the absorption systems with \(z_{\text{abs}}\lesssim z_{\text{em}}\) seen toward the bright, \(z_{\text{em}}\sim 3.91\), gravitationally lensed quasar APM 08279+5255 are presented. Two of the narrow-line systems, at \(z_{\text{abs}} = 3.8931\) and \(z_{\text{abs}} = 3.9135\), show absorptions from singly ionized species with weak or no N \(\text{V}\) and O \(\text{VI}\) absorptions at the same redshift. Absorption due to fine structure transitions of C \(\text{II}\) and Si \(\text{II}\) (excitation energies corresponding to, respectively, 156\(\mu\)m and 34\(\mu\)m) are detected at \(z_{\text{abs}} = 3.8931\). Excitation by IR radiation is favored as the column density ratios are consistent with the shape of APM 08279+5255 IR spectrum. The low-ionization state of the system favors a picture where the cloud is closer to the IR source than to the UV source, supporting the idea that the extension of the IR source is larger than \(\sim 200\) pc. The absence of fine structure lines at \(z_{\text{abs}} = 3.9135\) suggests that the gas responsible for this system is farther away from the IR source. Abundances are \(\sim 0.01\) and 1 \(Z_\odot\) at \(z_{\text{abs}} = 3.913\) and 3.8931 and aluminum could be over-abundant with respect to silicon and carbon by at least a factor of two and five. All this suggests that whereas the \(z_{\text{abs}} = 3.8931\) system is probably located within 200 pc from the QSO and ejected at a velocity larger than 1000 km s\(^{-1}\), the \(z_{\text{abs}} = 3.9135\) system is farther away and part of the host-galaxy.

Several narrow-line systems have strong absorption lines due to C \(\text{IV}\), O \(\text{VI}\) and N \(\text{V}\) and very low neutral hydrogen optical depths. This probably implies metallicities \(Z \geq Z_\odot\) although firm conclusion cannot be drawn as the exact value depends strongly on the shape of the ionizing spectrum. The C \(\text{IV}\) broad absorption has a complex structure with mini-BALs (width \(\lesssim 1000\) km s\(^{-1}\)) and narrow components superposed on a continuous absorption of smaller optical depth. The continuous absorption is much stronger in O \(\text{VI}\) indicating that the corresponding gas-component is of higher ionization than the other components in the flow and that absorption structures in the BAL-flow are mainly due to density inhomogeneities. There is a tendency for mini-BALs to have different covering factors for different species. It is shown that a few of the absorbing clouds do not cover all the three QSO images, especially we conclude that the \(z_{\text{abs}} = 3.712\) system covers only image C.

Finally we identify narrow components within the BAL-flow with velocity separations within 5 km s\(^{-1}\) of the O \(\text{VI}\), N \(\text{V}\) and Si \(\text{IV}\) doublet splittings suggesting that line driven radiative acceleration is an important process to explain the out-flow.

Key words: galaxies: quasars: absorption lines – galaxies: quasars: individual: APM 08279+5255 – galaxies: halos – galaxies: ISM

1. Introduction

The gravitationally lensed high-redshift Broad Absorption Line (BAL) QSO APM 08279+5255 has been given tremendous interest since its discovery by Irwin et al. (1998) as it is one of the most luminous objects in the universe even after correction for gravitational amplification. Based on the position of the emission lines, Irwin et al. (1998) derived a redshift \(z_{\text{em}} = 3.87\). A probably better estimate of the systematic redshift comes from the detection of CO(4–3) emission at \(z_{\text{em}} = 3.9114\pm0.0003\) by Downes et al. (1999).

Imaging of the field reveals two main components (Irwin et al. 1998; Ledoux et al. 1999) separated by 0.378\(\pm\)0.001 arcsec as measured on HST/NICMOS data (Ibata et al. 1999) and of relative brightness \(f_B/f_A = 0.773\pm0.007\). The HST images reveal the presence of a third object C with \(f_C/f_A = 0.175\pm0.008\), located in between A and B and almost aligned with them. The PSF fits on the three objects are consistent with the three components being point-sources and the colors are similar within the uncertainties suggesting that C is a third image of the quasar (Ibata et al. 1999; Egami et al. 2000). A high-resolution high signal-to-noise ratio spectrum of APM 08279+5255, covering the wavelength range 4400–10000\(\text{Å}\) was obtained using the
Keck telescope and made available to the Astronomy community for analysis (Ellison et al. 1999a,b). This spectrum, though complicated by the combination of light traveling along three different sight lines, is a unique laboratory for studying the intervening and associated absorption systems.

It is well known that the origin of associated systems (systems with $z_{\text{abs}} \sim z_{\text{em}}$) cannot be inferred directly from their position in the spectrum. Indeed, absorption can arise from (i) gas ejected by the central engine at velocity as high as 60000 km s$^{-1}$ and nonetheless physically located very close to the source of ionizing photons (e.g. the $z_{\text{abs}} = 2.24$ “mini-BAL” towards Q 2343+125 at $z_{\text{em}} = 2.515$; Hamann et al. 1997a) or from (ii) gas associated with the host-galaxy or with members of a galaxy cluster surrounding the quasar. The distinction can be made in terms of physical properties. The systems belonging to the first class are characterized by high metal enrichment, high-ionization parameters, broader line profiles, partial coverage and time variability (Barlow et al. 1992; Petitjean et al. 1994; Savaglio et al. 1994; Hamann 1997; Hamann et al. 1997b; Barlow & Sargent 1997; Ganguly et al. 1998; Papovich et al. 1999). The second class of absorber is characterized by classical properties of intervening systems such as low metallicities (typically 0.01 to 0.1 of solar) and undisturbed kinematics.

In this study we investigate the nature and physical properties of $z_{\text{abs}} \sim z_{\text{em}}$ systems toward APM 08279+5255. In Sect. 2, we describe the data and the grids of photoionization models we use to infer ionizing conditions in the absorbing gas. We analyse a probably intervening metal line system very close to the emission redshift in Sect. 3. The nature of narrow-line systems with low-ionization conditions are investigated in Sect. 4. Sect. 5 describes the high-ionization narrow-line systems. In Sect. 6, we analyse the nature of the BAL outflow and in Sect. 7 we suggest the presence of “line-locking” among narrow components in the BAL flow. A summary is given in Sect. 8.

### 2. Data and photoionization models

A spectrum of the $z_{\text{em}} = 3.91$ quasar APM 08279+5255 was obtained with the HIRES echelle spectrograph at the 10m Keck-I telescope (Ellison et al. 1999a,b). This data was made public together with a low-resolution spectrum of the quasar and a high-resolution spectrum of a standard star. We have corrected the high-resolution spectrum of APM 08279+5255 for small discontinuities in the continuum, which are probably due to the inappropriate merging of different orders. These discontinuities have been recognized by comparing the high and low-resolution spectra. The latter has also been used for normalization of the high-resolution data. Atmospheric absorption features were identified from the standard star spectrum. We have measured the final spectral resolution by fitting the narrow atmospheric absorption lines which are free of blending. We find $FWHM \sim 8$ km s$^{-1}$ ($b \sim 4.8$ km s$^{-1}$) at 6900 Å, $R = 37500$, and use this value throughout the paper.

Grids of photoionization models using the code Cloudy (Ferland 1996) have been constructed. The cloud is a plane parallel slab of uniform density, solar chemical composition and neutral hydrogen column densities $N(H^1) = 10^{16}$ cm$^{-2}$ (see below) photo-ionized by the QSO radiation. The spectral energy distribution of APM08279+5255 is not known in the UV/X-ray energy range. We use the standard AGN spectrum provided by Mathews & Ferland (1987) and also consider the effect of screening the ionizing spectrum by optically thick clouds to take into account the fact that BALs are X-ray quiet (Green & Mathur 1996). The resulting column densities of various species, for different ionizing spectra, along a line-of-sight perpendicular to the slab are given in Fig. 1.

### 3. The intervening system at $z_{\text{abs}} = 3.8576$

This system is revealed by strong C IV and hydrogen Lyman series lines. It is at higher redshift than the main component of the BAL out-flowing gas. Moderately saturated C IIIλ977 and C IV absorptions are seen whereas Si IIIλ1206 and Si IV, although present, are weak (see Fig. 2). Both C IV and C IIIλ977 profiles suggest the presence of 5 distinct components. Only the highest velocity component shows absorption due to higher hydrogen Lyman series transitions. The expected positions of O VI is in the wavelength range of the very strong O VI BAL.

Column densities estimated from Voigt profile fitting are given in Table 1 for different species. Note that the C IV doublet ratio is consistent with complete coverage of the background source (see below). The neutral hydrogen column density at $z_{\text{abs}} = 3.8574$ is well defined by higher Lyman series absorption lines. If we assume the QSO is the ionizing source we derive $log U = -2.5$ from the C III and C IV column densities and the absence of singly ionized species. Models with solar metallicities produce C III and C IV column densities two orders of magnitude larger than what is observed (see Fig. 1). This clearly suggests that metallicities are of the order of $[C/H] \simeq 0.01 [C/H]_{\odot}$, similar to what is usually derived for intervening systems. It is likely that this system does not belong to the QSO environment.

### Table 1. Parameters for the system at $z_{\text{abs}}=3.8568$

| Species | $z$ | $N$(cm$^{-2}$) | $b$(km s$^{-1}$) |
|---------|----|-------------|----------------|
| H I     | 3.8574 | $1.32 \pm 0.13 \times 10^{16}$ | 17.41 $\pm 1.13$ |
| C III   | 3.8557 | $3.13 \pm 0.38 \times 10^{12}$ | 20.85 $\pm 1.81$ |
|         | 3.8564 | $7.95 \pm 0.50 \times 10^{12}$ | 12.43 $\pm 0.36$ |
|         | 3.8568 | $2.08 \pm 0.12 \times 10^{13}$ | 10.67 $\pm 0.13$ |
|         | 3.8571 | $2.41 \pm 0.34 \times 10^{12}$ | 7.25 $\pm 0.70$ |
|         | 3.8574 | $1.16 \pm 0.07 \times 10^{13}$ | 12.57 $\pm 0.72$ |
| C IV    | 3.8557 | $3.34 \pm 0.24 \times 10^{12}$ | 20.85 $\pm 1.81$ |
|         | 3.8564 | $1.09 \pm 0.03 \times 10^{13}$ | 12.43 $\pm 0.36$ |
|         | 3.8568 | $3.76 \pm 0.43 \times 10^{13}$ | 10.67 $\pm 0.13$ |
|         | 3.8571 | $2.67 \pm 0.28 \times 10^{12}$ | 7.25 $\pm 0.70$ |
|         | 3.8574 | $6.39 \pm 0.30 \times 10^{12}$ | 12.57 $\pm 0.72$ |
| Si IV   | 3.8567 | $1.27 \pm 0.07 \times 10^{12}$ | 9.73 $\pm 0.67$ |
|         | 3.8574 | $6.69 \pm 0.05 \times 10^{11}$ | 5.44 $\pm 0.63$ |
4. Intrinsic systems with narrow and low-ionization lines

4.1. The $z_{\text{abs}} = 3.8931$ complex

Absorption profiles of some of the important transitions from this complex are given in Fig. 3. In what follows, we concentrate on the component at $v \sim 0$ km s$^{-1}$, which shows absorption due to low ionization lines: Al II, Al III, Si II, Si II*, C II and C II*. In addition, there are strong absorption lines at the expected positions of N III λ989 and C III λ977 with profiles similar to that of C IV and Si IV. It is however very difficult to rule out contamination by intervening Lyman-α systems. There is a feature at the expected position of O VI λ1031. However, as O VI λ1037 is
heavily blended, it is difficult to establish the presence of O\textsc{vi} in this system. N\textsc{v} absorption is present and weak (see Fig. 3).

4.1.1. Partial covering factor

The flat bottom and the presence of other Lyman series lines show that the Lyman-\(\alpha\) line is saturated. However, it is apparent on Fig. 5 that there is some residual flux in the core of the Lyman-\(\alpha\) line. Similar residuals are seen at the bottom of Si\textsc{iv}1309 and C\textsc{iv}1548. Residual flux is expected in case one of the three lines of sight is not intercepted by the absorbing cloud. However the relative brightnesses of the components are \(f_B/f_A \sim 0.773\) and \(f_C/f_A \sim 0.175\) (Ibata et al. 1999). Therefore, under the above assumption, at least 10% residual flux is expected, much larger than the 3% observed. This clearly suggests instead that the absorbing gas is located outside the BLR and that it covers only 97% of the background source (BLR+continuum+scattered light). We use the C\textsc{iv}, Si\textsc{iv} and Al\textsc{iii} doublets to estimate the covering factor of these species applying the method described in Srianand \& Sankaranarayanan (1999). The results are shown in Fig. 6. The covering factor of the C\textsc{iv} and Si\textsc{iv} component at \(v \sim 0\) \(\text{km s}^{-1}\) is about 0.95 whereas the corresponding value for Al\textsc{iii} is 0.80.

For simplicity and because the residual is small, we assume complete coverage while estimating the column density of H\textsc{i}. We find log \(N(\text{H} \textsc{i}) = 15.9\), suggesting that the partial Lyman limit detected in the rest frame of the QSO (Irwin et al. 1998) is most certainly not due to this system.

The covering factor of the singly ionized phase can be estimated using the numerous Si\textsc{ii} lines. In particular, the Si\textsc{ii}1260 and Si\textsc{ii}1304 absorption lines are redshifted beyond the QSO Lyman-\(\alpha\) emission line. The Si\textsc{ii}1260 line is blended with C\textsc{iv}1548 at \(z_{\text{abs}} = 2.9833\) and we use C\textsc{iv}1550 to remove the contamination. In the lower panel of Fig. 5 the best Si\textsc{ii}1260 fit, after removal of the C\textsc{iv} contribution, is plotted together with the Si\textsc{ii}1304 profile appropriately scaled to Si\textsc{ii}1260 for a covering factor of \(f_c = 0.8\). This covering factor is consistent with the value derived from the Al\textsc{iii} doublet. In the top panel of Fig. 5 the Si\textsc{ii}\*1309 profile is plotted together with the scaled profile of Si\textsc{ii}\*1264 for two values of the covering factor. The best value is \(f \sim 0.54\), however as the Si\textsc{ii}\*1309 is weak, a value of 0.8 is well within the 1\(\sigma\) error. Thus, the data is consistent with both Si\textsc{ii} and Si\textsc{ii}\* absorptions having similar covering factors \(f_c \sim 0.8\).

The column densities given in the fourth column of Table 2 are obtained by integrating the optical depth over the velocity range covered by the absorptions after taking into account the covering factors derived above. Note that the C\textsc{iv} column density is unreliable due to blending with other lines as well as contamination of C\textsc{iv}1550 by C\textsc{iv}1548 at \(z_{\text{abs}} = 3.901\). Results from single component Voigt-profile fits are given in the second column of the Table 2.

4.1.2. Excitation of the fine-structure levels

The presence of several absorption lines from excited fine-structure levels of Si\textsc{ii} and C\textsc{ii} is a unique opportunity to
study the physical properties of the absorbing gas. Two main excitation processes are at play: radiative excitation by an IR radiation field and collisional excitation mainly by electrons.

Let us first consider radiative excitation. In that case, 

$$N(X^*) / N(X) = 2 \left( \frac{\bar{n}_\lambda}{1 + \bar{n}_\lambda} \right) $$

(1)

where $X$ is either C II or Si II and $\bar{n}_\lambda$ is given by

$$\bar{n}_\lambda = \frac{I(\nu) \lambda^3}{8\pi hc} $$

(2)

where $I(\nu)$, in erg cm$^{-2}$ s$^{-1}$ Hz$^{-1}$, is the flux of energy density integrated over all directions. From the available IRAS fluxes and the sub-millimeter observations by Lewis et al. (1998), the flux at the excitation energy of Si II (0.036 eV) in the rest frame of the absorber is 0.1 Jy. Assuming the IR emitting region to be a point, $z = 3.910$, $H_o = 75$ km s$^{-1}$ Mpc$^{-1}$ and $q_0 = 0.5$, we obtain,

$$\bar{n}_\lambda = \frac{0.0038}{r(kpc)^2} \left( \frac{1}{k} \right) $$

(3)

where $r$ is the distance of the cloud from the ionizing source and $k$ is the magnification factor due to gravitational lensing. From Eqs. (1) and (2) we derive,

$$r(kpc)^2 = \frac{2}{N(Si II) / N(Si II^*) - 1} \times \frac{0.0038}{k} $$

(4)

The IR flux at the excitation energy of C II (0.008 eV) is 0.016 Jy so that

$$\bar{n}_\lambda(C II^*) = 15.18 \times \bar{n}_\lambda(Si II^*) $$

(5)

Therefore if radiative excitation is at play, we should observe,

$$\frac{N(C II)}{N(C II^*)} = \left[ \frac{N(Si II)}{N(Si II^*)} + 7.09 \right] \times 0.063. $$

(6)

As $N(Si II)/N(Si II^*) \sim 3.5$, the radiative excitation predicts $N(C II)/N(C II^*) \sim 0.67$ when the observed ratio is 0.66. This strongly suggests that indeed excitation by IR radiation is important. For $k = 1$, we obtain an upper limit on the distance of the cloud from the IR source, $r < 150$ pc. If the magnification

\begin{table}[h]
\begin{center}

Al iii & 6.23±0.15 × 10$^{12}$ & 9.07±0.24 & 1.04×10$^{13}$ \\
\end{tabular}
\end{center}
\end{table}
factor is as high as 90, as suggested by the probable presence of the third image (Ibata et al. 1999; Egami et al. 1999), the distance could be as small as 15 pc.

Let us consider now the case of pure collisional excitation. Note that excitation by hydrogen atoms is unimportant in the case of optically thin clouds. Deexcitation is due to spontaneous emission as well as particle collisions. The necessary relationships to estimate the population ratios as a function of temperature and density are taken from Bahcall & Wolf (1968). For Si ii the collisional excitation rate is, \(3.32 \times 10^{-7} T_4^{0.5} \exp(-413.4/T)\) cm\(^3\)s\(^{-1}\), the collisional deexcitation rate is, \(1.66 \times 10^{-7} T_4^{0.5}\) cm\(^3\)s\(^{-1}\) and the spontaneous radiative deexcitation rate is \(2.13 \times 10^{-4}\) s\(^{-1}\). For C ii the above rates are respectively, \(6.20 \times 10^{-8} T_4^{-0.5} \exp(-91.25/T)\) cm\(^3\)s\(^{-1}\), \(3.10 \times 10^{-8} T_4^{-0.5}\) cm\(^3\)s\(^{-1}\) and \(2.36 \times 10^{-6}\) s\(^{-1}\). Here, \(T_4\) is the temperature expressed in units of \(10^4\) K.

In Fig. 6 are plotted the ratios \(N(\text{Si} \, \text{ii}^*)/N(\text{Si} \, \text{ii})\) and \(N(\text{C} \, \text{ii}^*)/N(\text{C} \, \text{ii})\), of excited to ground state column densities as a function of temperature for three different values of the electronic density. In order to reproduce the observed ratios (indicated by horizontal dashed lines in Fig. 6), the electron density has to be larger than \(100\) cm\(^{-3}\) and the temperature greater than \(320\) K. As can be seen from Fig. 6 there is no stringent constraint on the electron density when the electron temperature of the gas is low. Note that although it would be surprising to find such a small temperature in an optically thin cloud located in the vicinity of the quasar, this is possible if the metallicity of the gas is well above solar (e.g. Petitjean et al. 1994). In case the gas is warm, from the width of the absorption lines, we derive an upper limit on the temperature of \(4.6 \times 10^4\) K which gives an upper limit on the density of \(500\) cm\(^{-3}\).

Is there any way to choose between the two processes discussed above? The small distance inferred in case of pure radiative excitation together with the low-ionization state of the gas may be at odd with the proximity of a very powerful source of ionizing radiation. From the low spectral resolution spectrum, we estimate the flux at the Lyman limit in the rest frame of the absorber to be \(3 \times 10^{-16}\) erg s\(^{-1}\)cm\(^{-2}\)Å\(^{-1}\). This corresponds to a luminosity at the Lyman limit of \(L_{\nu} = 4.28 \times 10^{30}\) erg Hz\(^{-1}\)s\(^{-1}\). Assuming a flat spectrum and integrating \(L(\nu)/\hbar \nu\) over the energy range 1 to 20 Ryd, we estimate the number of ionizing photons per unit time emitted by the quasar, \(Q = 2 \times 10^{57}/k\), where \(k\) is the magnification factor. Thus, the distance \(r\) between the cloud and the quasar is

\[
 r = \frac{24.3}{(k n_{100} U_{-2})} \text{ kpc} \tag{7}
\]

where \(n_{100}\) is the particle density in units of \(10^2\) cm\(^{-3}\), and \(U_{-2}\) is the dimensionless ionization parameter in units of \(10^{-2}\). The latter is the ratio of the density of ionizing photons to the hydrogen density. The H i, Si ii and C ii column densities derived in this system are consistent with \(\log U \sim -2\) (see Table 2 and Fig. 1). Even for metallicities larger than 10 \(Z_\odot\), \(\log U < -1\). As \(n_{100} < 5\) and \(k < 90\), we conclude that \(r > 350\) pc. This lower limit can be reconciled with the distance inferred from the IR excitation if (i) contrary to the UV source, the IR source is not lensed which does not seem to be the case (see Downes et al. 1999) or (ii) the cloud is closer to the IR source than to the UV source. Indeed Downes et al. (1999) have shown that the molecular gas and the dust are located in a nuclear disk of radius 90 to 270 pc. The absorption system could be at 350 pc from the central UV source and still very close to the IR emitting disk.

Let us now assume that the cloud is at a large distance from the quasar and that the excitation is purely collisional. In that case, the electronic density must be larger than \(100\) cm\(^{-3}\). Rapid variations of the density on very small scales could imply variations of the Si ii/Si ii\(^*\) ratio from one line-of-sight to the other. If we apply a typical ionization correction, \(H\,\prime/H^+ = 4 \times 10^{-3}\), to the \(H\,\prime\) column density derived above (see Table 2), we obtain \(N(\text{H}) = 2 \times 10^{18}\) cm\(^{-2}\) and assuming \(n > 100\) cm\(^{-3}\), we infer a dimension of the cloud along the line-of-sight of \(\sim 0.006\) pc. Reverberation studies of the nearby AGN NGC 5548 suggest that the size of the BLR could be in the range 10 to 20 lt days (e.g. Krolik & Done 1995; Korista et al. 1995). It is also known that the size of the BLR scales with luminosity as \(L^{0.5}\). From the UV and optical spectra we estimate that APM 0827+5255 is at least \(500/k\) times brighter than NGC 5548. If we apply the luminosity scaling then the radius of the BLR of APM 0827+5255 is of the order of \(\sim 0.3/\sqrt{k}\) pc. Thus in order to cover 97% of the background source, the transverse dimension of the cloud should be \(\sim 50/\sqrt{k}\) times larger than the dimension along the line-of-sight. As \(k\) could be as large as 100, the two dimensions

![Fig. 6. Column density ratios \(N(X^*)/N(X)\) for C ii and Si ii in the excited and ground states as a function of temperature. For each species, the three solid lines correspond to pure collisional excitation with electronic densities \(n_e = 100, 500\) and \(10^5\) cm\(^{-3}\) from the lower to the upper curve. Horizontal dotted lines indicate observed values with \(\pm 1\sigma\) errors.](image-url)
could be of the same order of magnitude. The cloud is therefore very small.

4.1.3. Photoionization model

In this section, we discuss the ionization state of the gas in more detail. Fig. 1 shows the results of models with solar metallicity assuming different ionizing spectra, either an unattenuated Mathews & Ferland (1987) spectrum or the same spectrum attenuated by an ionized hydrogen and helium slab with log $U = -1$ and H I column density of $10^{17} - 18$ cm$^{-2}$. The resultant spectra are given in panel (d) of Fig. 1. It is apparent that the absorption is most important at the He II edge. This mimics the presence of the BAL outflow along the line-of-sight. As an illustration, the number of ionizing photons is reduced by a factor 6 due to the presence of a screen with log $N$(H I) = 18.

In models with unattenuated ionizing radiation, the observed $N$(Al III)/$N$(Al II), $N$(Si IV)/$N$(Si II) and $N$(C IV)/$N$(C II) ratios suggest consistently log $U = -2.0$, −2.2 and −2.3 and [Al/H] = 3.2 [Al/H]⊙, [C/H] = 0.5 [C/H]⊙ and [Si/H] = 1.6 [Si/H]⊙. Models with ionizing radiation attenuated by a screen with log $N$(H I) = $10^{17}$ cm$^{-2}$ give log $U = -2.2$, and [Al/H] = 1.7 [Al/H]⊙, [C/H] = 0.5 [C/H]⊙ and [Si/H] = 0.9 [Si/H]⊙.

The most important effect of attenuation is that the N v column density decreases with increasing attenuation due to the paucity of photons of energy larger than the N IV ionization potential. In the case of unattenuated ionizing spectrum and assuming solar abundances, the model predicts log $N$(N v) $> 13.2$ which is at least a factor of 3 larger than the observed value.

| Species | $z$ | $N$(cm$^{-2}$) | $b$(km/s) |
|---------|-----|----------------|-----------|
| H I     | 3.9135 | $1.04 \pm 0.15 \times 10^{17}$ | $18.57 \pm 0.77$ |
| C II    | 3.9135 | $1.28 \pm 0.02 \times 10^{13}$ | $12.51 \pm 0.27$ |
| C II*   | 3.9135 | $\leq 5.30 \times 10^{12}$ | ... |
| C IV    | 3.9133 | $8.13 \pm 0.20 \times 10^{13}$ | $11.67 \pm 0.47$ |
| C IV    | 3.9135 | $4.83 \pm 0.17 \times 10^{13}$ | $16.49 \pm 0.49$ |
| C IV    | 3.9138 | $1.53 \pm 0.13 \times 10^{13}$ | $16.71 \pm 3.07$ |
| Si II   | 3.9135 | $1.35 \pm 0.07 \times 10^{12}$ | $11.50 \pm 0.70$ |
| Si II*  | 3.9135 | $\leq 8.40 \times 10^{11}$ | ... |
| Si IV   | 3.9133 | $3.69 \pm 0.10 \times 10^{13}$ | $9.48 \pm 0.26$ |
| Si IV   | 3.9135 | $2.04 \pm 0.04 \times 10^{13}$ | $12.70 \pm 0.21$ |
| Si IV   | 3.9138 | $4.53 \pm 0.22 \times 10^{13}$ | $10.03 \pm 0.49$ |
| N v     | 3.9135 | $\leq 10^{12}$ | ... |
| Al ii   | 3.9135 | $8.64 \pm 0.03 \times 10^{11}$ | $12.21 \pm 0.55$ |
| Al ii   | 3.9135 | $2.15 \pm 0.06 \times 10^{12}$ | $12.68 \pm 0.45$ |

Attenuation by a slab with neutral column density as large as log $N$(H I) = 18 is ruled out, however, as in that case log $N$(N v) = 11 instead of 12.7 observed.

In conclusion, if the shape of the ionizing radiation from the QSO is similar to the Mathews & Ferland (1987) spectrum, then the data is consistent with attenuation of the ionizing flux by a screen with log $N$(H I) = 17. Absolute metallicity is probably very close to solar which is typical of associated absorption systems (e.g. Hamann & Ferland 1993; Petitjean et al. 1994; Petitjean & Srianand 1999; Hamann & Ferland 1999 for a recent review). However there is an indication that Carbon is under-abundant and Aluminum over-abundant compared to Silicon.

4.2. The $z_{abs} = 3.9135$ complex

The redshift of this system is very close to the CO emission redshift, $z_{CO} = 3.9114$ (Downes et al. 1999); the difference is only $\sim 130$ km s$^{-1}$ whereas the width of the CO line is 480 km s$^{-1}$ and the total width of the saturated part of the associated Lyman-$\alpha$ line is 300 km s$^{-1}$. Three distinct sub-systems are seen in Si IV and C IV. The strongest component in this complex has associated absorption from C II, C IV, Si II, Si IV, Al II, Al III and Lyman-$\alpha$ (see Fig. 7). Unlike what is observed at $z_{abs} = 3.8931$, the Lyman-$\alpha$ line goes to zero indicating complete coverage. This is confirmed by the Si IV and Al III doublets. Using the Lyman series, we estimate the neutral hydrogen column density, log $N$(H I) = $17.0 \pm 0.14$ (see Table 3). This is consistent with this system being responsible for the partial Lyman limit absorption seen in the low-resolution spectrum of APM 08279+5255. The Si IV and C IV doublets are well fitted by a model with three components; all the absorption lines due to singly ionized species are fitted with a single component. N v and O VI are clearly absent. There is no absorption from Si II* down to a 2$\sigma$ upper limit of log $N$(Si II*) $< 11.9$. The C IV* line is redshifted at the same position as C IV$\lambda 1548$ at $z_{abs} = 3.2388$. We
estimate a 2σ upper limit on \(N(C\,\text{II}^*)\) after subtraction of the \(C\,\text{IV}\) profile, \(\log N(C\,\text{II}^*) < 12.7\). The ratio of \(C\,\text{II}^\text{+}\) to \(C\,\text{II}\) in this system is at least a factor 4 smaller than in the \(z_{\text{abs}} = 3.8931\) system discussed previously. This suggests that this cloud has to be farther away from the IR source than \(z_{\text{abs}} = 3.8931\) cloud. For electron temperatures less than \(3 \times 10^4\) K the observed limit also suggests that the electronic density is less than \(20\,\text{cm}^{-3}\).

The \(N(\text{Al}\,\text{II})/N(\text{Al}\,\text{III})\) column density ratio in the two systems at \(z_{\text{abs}} = 3.8931\) and \(3.9135\) can be used to compare their ionization states. \(N(\text{Al}\,\text{II})/N(\text{Al}\,\text{III}) = 0.40\) at \(z_{\text{abs}} = 3.9135\) while the allowed range at \(z_{\text{abs}} = 3.8931\) is 0.06–0.10 (after taking into account covering factor effects). Note that the \(N(C\,\text{II})/N(C\,\text{IV})\) ratio is also larger at \(z_{\text{abs}} = 3.9135\). From Fig. 7 of Petitjean et al. (1994) it is clear that when \(N(\text{H}\,\text{I}) < 10^{17}\,\text{cm}^{-2}\), \(N(\text{Al}\,\text{II})/N(\text{Al}\,\text{III})\) is approximately independent of the neutral hydrogen column density (for a given ionizing spectrum) and depends only on the ionization parameter. Therefore, the ionization parameter of the \(z_{\text{abs}} = 3.9135\) system is slightly smaller than that of the \(z_{\text{abs}} = 3.8931\) system.

To discuss this system in more detail, we can use the models of Fig. 1b, scaling the column densities with abundances. The \(N(\text{Al}\,\text{II})/N(\text{Al}\,\text{II})\, N(\text{C}\,\text{II})/N(\text{C}\,\text{IV})\) and \(N(\text{Si}\,\text{III})/N(\text{Si}\,\text{IV})\) ratios suggest, log \(U = −2.83, −2.6\) and \(−2.3\) respectively. The range of ionization parameters reflects the uncertainties. If we use the mean ionization parameter, log \(U = −2.5\), the model suggests \([C/H] = 0.02\, [C/H]_\odot, [Si/H] = 0.01\, [Si/H]_\odot\) and \([Al/H] = 0.23\, [Al/H]_\odot\). Though the average abundance in this system is similar to intervening systems at large redshift, it seems that Aluminum is largely enhanced compared to Carbon and Silicon. Such peculiar abundance pattern has already been noted by Ganguly et al. (1999).

All this suggests that whereas the \(z_{\text{abs}} = 3.8931\) system must be located within 200 pc from the QSO and ejected at a velocity larger than 1000 km s\(^{-1}\), the \(z_{\text{abs}} = 3.9135\) system must be farther away and part of the host-galaxy.

### 5. High-ionization narrow-line systems

In this section we study the high-ionization narrow-line associated systems, defined as well detached systems with Lyman-\(\alpha\) apparent optical depths much smaller than that of \(O\,\text{VI}\) and \(N\,\text{V}\) (see Fig. 8). There are two main complexes at \(z_{\text{abs}} \approx 3.90\) and \(z_{\text{abs}} \approx 3.917\). We concentrate on well defined strong components.

#### 5.1. \(z_{\text{abs}} = 3.8997\)

Column densities are estimated using the apparent optical depth method (Savage & Sembach 1991). The results are given in Table 4 along with the velocity intervals over which the column density is estimated. The residual intensities in both components of the \(N\,\text{V}\) doublet and the \(O\,\text{VI}\) and \(O\,\text{V}\) (see Fig. 8) components are consistent with complete coverage. Unlike \(O\,\text{VI}\), \(N\,\text{V}\) lines are not heavily saturated. As can be seen from Fig. 8 the \(C\,\text{IV}\,\lambda 1550\) component is heavily affected by atmospheric absorption. We estimate a lower limit on the \(C\,\text{IV}\) column density using the \(C\,\text{IV}\,\lambda 1548\) profile and assuming complete coverage. There is a strong absorption feature at the expected position of \(C\,\text{III}\,\lambda 977\), the profile of which is very similar to that of \(C\,\text{IV}\). As we cannot rule out contamination by intervening Lyman-\(\alpha\) absorption, the \(C\,\text{III}\) column density should be considered as an upper limit. As can be seen from Fig. 8 the associated Lyman-\(\alpha\) absorption is very weak in this component. In addition, this line falls in the wavelength range over which \(N\,\text{V}\) BAL absorption is present and coincides with the expected position of the \(N\,\text{V}\,\lambda 1242\) absorption from a complex at \(z_{\text{abs}} = 3.795\), which has ubiquitous absorption due to \(C\,\text{IV}\) and \(Si\,\text{IV}\) (see also next section). Therefore the \(H\,\text{I}\) column density given in Table 4 is most certainly an upper limit.

### Table 4. Parameters for the high-ionization narrow line systems

| \(z_{\text{abs}}\) | Species | \(N(\text{cm}^{-2})\) | \(v(\text{km s}^{-1})\) |
|-----------------|---------|----------------|----------------|
| 3.8997 | \(H\,\text{I}\) | \(\leq 3.7 \times 10^{12}\) | -20.18 |
| | \(N\,\text{V}\) | \(2.85 \times 10^{14}\) | ..... |
| | \(C\,\text{IV}\) | \(\geq 2.3 \times 10^{14}\) | ..... |
| | \(C\,\text{III}\) | \(\geq 1.0 \times 10^{14}\) | ..... |
| | \(O\,\text{VI}\) | \(\geq 9.8 \times 10^{14}\) | ..... |
| 3.9010 | \(H\,\text{I}\) | \(\leq 6.3 \times 10^{12}\) | -14.18 |
| | \(N\,\text{V}\) | \(6.91 \times 10^{13}\) | ..... |
| | \(C\,\text{III}\) | \(\leq 3.0 \times 10^{13}\) | ..... |
| | \(O\,\text{VI}\) | \(\geq 7.3 \times 10^{14}\) | ..... |
| 3.9170 | \(H\,\text{I}\) | \(2.60 \times 10^{13}\) | -50.18 |
| | \(N\,\text{V}\) | \(\leq 1.0 \times 10^{14}\) | ..... |
| | \(O\,\text{VI}\) | \(9.7 \times 10^{14}\) | ..... |

Fig. 8. High-ionization narrow-line systems. The vertical dashed lines mark the strong components discussed in the text. The CO emission redshift is \(z_{\text{em}} = 3.9114\).
5.2. $z_{\text{abs}} = 3.9010$

This component shows strong O iv absorption with profiles consistent with complete coverage. The Lyman-α component coincides with the expected position of the N v at 1242 absorption from the complex at $z_{\text{abs}} = 3.795$. Thus, the H i column density given in Table 4 is an upper limit. From Fig. 8 it can be seen that N v at 1242 from this system coincides with N v at 1238 at $z_{\text{abs}} = 3.9170$. Thus we estimate the N v column density using the N v at 1238 line only. As noted before, C iv at 1550 is heavily affected by atmospheric absorption; C iv at 1548 coincides with C iv at 1550 at $z_{\text{abs}} = 3.9135$ (see Figs. 7 and 8) preventing us to estimate the C iv column density in this system. There is a strong line at the expected position of C iii at 977. We estimate an upper limit of the C iii column density assuming complete coverage.

5.3. $z_{\text{abs}} = 3.9170$

The saturated O vi lines have no residual flux so the absorbing cloud completely covers the background source. The O vi at 1037 line is blended with a strong line most probably due to an intervening cloud. The lower limit on the O vi column density is estimated using the O vi at 1031 line only. As discussed before the N v at 1238 line is blended with the N v at 1242 line at $z_{\text{abs}} = 3.9010$ and the N v at 1242 line is blended with Mg ii at 2796 at $z_{\text{abs}} = 1.18$. It is therefore difficult to estimate the N v column density accurately. We obtain an upper limit using the N v at 1238 profile. Though the C iv absorption is quite strong, both lines of the doublet are badly blended with atmospheric features.

5.4. Modeling

The column densities derived in the three systems are given in Table 4. The observed column densities of H i, C iv, N v and O vi are typical of associated absorption systems (Petitjean et al. 1994; Hamann 1997; Petitjean & Srianand 1999).

We run photoionization models using the “Optimize” command available in “Cloudy” to derive the best values for the ionization parameter and heavy element abundances. For the Mathews & Ferland (1987) ionizing spectrum we obtain log $U = -0.87$ and $Z = 180Z_{\odot}$ for the $z_{\text{abs}} = 3.8997$ system and log $U = -0.74$ and $Z(O,N) = 14Z_{\odot}$ for the $z_{\text{abs}} = 3.9010$ system.

However, it is known that BALQSOs are X-ray quiet with optical to X-ray spectral index $\alpha_{\text{OX}} \geq 1.9$ (Green & Mathur; 1996) while the Mathews & Ferland spectrum has $\alpha_{\text{OX}} = 1.40$. If we assume the spectra seen by the absorbing clouds to be steeper than the Mathews & Ferland spectrum then we obtain $Z = 5, 1.4, 0.5, 0.4 Z_{\odot}$ and $U = 0.3, 0.7, 1.2, 1.3$ for $\alpha_{\text{OX}} = 1.5, 1.7, 1.9$ and 2.1 respectively for the $z_{\text{abs}} = 3.8997$ system. The reason for this is that the number of photons available for ionization of C iv, N v and O vi decreases when $\alpha_{\text{OX}}$ increases. Therefore, it would be of first interest to measure $\alpha_{\text{OX}}$ for this quasar.

6. The BAL flow

The maximum observed ejection velocity of the C iv absorption is $\sim -12000$ km s$^{-1}$ relative to the systemic redshift $z_{\text{em}} = 3.911$. The BAL is of high-ionization: the O vi absorption is much stronger than the C iv one; N v is also conspicuous; weak Si iv absorption is seen in only a few components (especially those responsible for the strong C iv troughs at $\sim -9670$ km s$^{-1}$ and $\sim -4670$ km s$^{-1}$). The structure of the absorption profiles due to the out-flowing gas is complex as it breaks into components of different widths, depths and covering factors (see Fig. 9).

Weymann et al. (1991) have shown that the mean spectrum of BALQSOs shows two distinct and localized minima separated by about the velocity splitting of N v and Lyman-α (i.e. $\sim 5000$ km s$^{-1}$) located near velocities $-4700$ and $-10500$ km s$^{-1}$ relative to the emission redshift. Korista et al. (1993) have found that 22% of BALQSOs do show double troughs. These features suggest that radiative acceleration is important to generate the flows and the observed profiles are due to line-locking (Arav 1996 and references therein).

In APM 0827+5255, the two strongest troughs in the C iv profile are separated by $\sim 4900$ km s$^{-1}$ (see Figs. 2 and 9), smaller than the Lyman-α – N v velocity splitting. In between these two absorption troughs there are weak C iv absorption lines (resolved even in the low-resolution spectrum). From the shape of the red wing of the C iv emission line it is also apparent that the flux in the blue wing of the C iv emission line at $\sim 7461\AA$ is very close to the expected unabsorbed value (see Fig. 10). This suggests that the two strong troughs are well detached. It is very difficult to produce such a profile in models of out-flowing gas where the double structures are created by radiative processes which produce clustering in the velocity space keeping all absorbing atoms at the same physical location (see the fits to double troughs in Fig. 11 of Arav 1996). We thus believe that the two strong troughs are due to physically distinct absorbing components which are similar to mini-BAL systems seen in a few QSOs (e.g. Petitjean & Srianand 1999).

In what follows we consider smaller velocity intervals and investigate the profiles of different absorptions in more detail. The velocity are taken with respect to $z_{\text{em}} = 3.911$.

6.1. The broad C iv absorption at $v \approx -12400$ km s$^{-1}$

The two broad features at 7295 Å and 7305 Å correspond mostly to the two lines of a C iv doublet at $z_{\text{abs}} \sim 3.712$ ($v \approx -12400$ km s$^{-1}$ in Fig. 9). The profiles do not match exactly however. It is clear from Fig 11 that there is an extra absorption in the C iv at 1550 profile at $\sim -160$ km s$^{-1}$ from the center of the line. This absorption is tentatively identified as C iv at 1550 at $z_{\text{abs}} \approx 3.717$, the corresponding broad, albeit weak, C iv doublet at 1550 line is blended with the narrower Fe ii at 2600 complex from a Mg ii system at $z_{\text{abs}} = 1.81$. Most of the narrow absorption features seen in the C iv at 1548 and C iv at 1550 profiles are due to atmospheric absorptions.
Fig. 9. Broad absorptions due to various species. The origin of the velocity scale is taken at $z_{em} = 3.91$.

We believe, this absorption structure is real because of the good match between the profiles of the C iv lines in the red wings (see Fig. 11), and because the lines are located very near the centre of an echelle order and thus cannot be an artifact of imperfect order merging. This system is well detached from the rest of the BAL and therefore the continuum can be fitted accurately. The C iv absorption is most probably saturated as the residual intensities in both lines are similar. However they are equal to 0.87 which clearly indicates that the covering factor is surprisingly small, $\sim 0.13$. The C iv profiles, in the velocity range not affected by the narrow atmospheric absorption lines between $-100 \, \text{km \, s}^{-1}$ and $100 \, \text{km \, s}^{-1}$, can be fitted with a covering factor of 0.12 (see top panel in Fig. 11). The typical error in the covering factor is 0.02 (as the rms in the normalised continuum over this wavelength range is 0.02). From Fig. 10 it is apparent that this absorption, does not occur on top the C iv emission line. Thus the low coverage is most likely due to the fact that the absorbing gas does not cover one of the images of the very small continuum source. If the absorbing gas covers only image C, then we expect a covering factor of 0.09. The consistency with the observed value is an additional argument in favor of object C being the third image of the gravitationally lensed quasar. If true, this implies that a strong C iv absorption, with very little residual intensity, is expected in the spectrum of image C whereas very weak or no absorptions are expected.  

Fig. 10. Part of the low-resolution spectrum showing the Si iv and C iv emission lines. The solid line indicates the QSO continuum emission.
6.2. Absorptions in the range $-10000 < v < -9000$ km s$^{-1}$

In addition to the broad absorption seen in this wavelength range, there are a few narrow absorption lines identified as C IV doublets.

6.2.1. Narrow lines at $v \simeq -10030$ km s$^{-1}$

The system at $v \simeq -10030$ km s$^{-1}$ is defined by C IV, O VI, N v and Si iv narrow absorption lines. They are most probably associated with a strong Lyman-$\alpha$ line seen at the same velocity (see Fig. 12). Unlike other narrow systems seen over this wavelength range, the profile of the O VI absorption is well defined and less affected by blending. The equivalent widths of the C IV lines measured using a continuum defined locally, $w = 0.24$ and 0.13 Å, are consistent with a covering factor close to unity.

6.2.2. System at $v \simeq -9650$ km s$^{-1}$

This system is defined by strong and broad C IV and Si iv lines. There is an absorption line at the expected position of Si iii λ1206 with very similar velocity profile which leaves little doubt on the identification (see Fig. 12). The fit to the Si iv doublet gives a covering factor of $\sim 0.25$. For this value we estimate the column density of Si iv to be $\sim 10^{14}$ cm$^{-2}$. It is interesting to note that the residual intensities of Si iii λ1206 and Si iv are similar. If both absorptions are produced in the same region this means that the column density of Si iv is about a factor of 3 larger than that of Si iii.

As the continuum fitting in the Si iv region is accurate, the estimate of the covering factor is reliable. The low-resolution data indicates that the Si iv absorption is not located on top...
of the Si IV emission line. Thus, a partial covering factor has to be explained in terms of one or two of the multiple images not being covered. However, the covering factor we derive here is larger than what is expected if the gas covers only image C and smaller than the expected value if it covers only image B. This most certainly means that the absorbing gas covers at least two of the images and that the optical depths along different sight lines are different. Absorptions due to the C IV lines are strong and both have residual intensity $\sim 0.20$ (covering factor $f \sim 0.80$). Though this value is somewhat uncertain due to the non-uniqueness of the continuum fitting, it is larger than the value derived for Si IV. It has been observed already in some “mini-BALs” that covering factors vary from one transition to the other (see e.g. the $z_{\text{abs}} = 2.207$ system towards J2233-606, Petitjean & Srianand 1999). However, the interpretation of this in the present case is clearly that the ratio of the optical depths of Si IV and C IV along different sight-lines are different.

The Lyman-α line at about the same velocity is most certainly from an intervening system at $z_{\text{abs}} \sim 3.7584$ associated with two weak C IV and Si IV narrow components (marked by dotted lines at $-9440$ and $-9530$ km s$^{-1}$ on Fig. 12). The determination of the H I column density in the broad system is difficult as the higher Lyman series lines are expected to be broad and shallow if the covering factor is 0.25. However we note that the residual flux at the expected positions of Ly-6 and Ly-7 are smaller than 0.25 suggesting that these lines, if at all present, are not heavily saturated. We obtain an upper limit on $N(\text{H I})$ of $4 \times 10^{14}$ cm$^{-2}$ for an assumed covering factor of 0.25. For a Mathews & Ferland (1987) ionizing spectrum, the ionization parameter required to produce the observed Si IV to Si III column density ratio is $\log U \simeq -2.00$. This suggests that the absorbing gas is weakly ionized compared to the systems we have discussed above. The model needs $[\text{Si/H}] \geq 20[\text{Si/H}]_{\odot}$ in order to reproduce the column densities. Note that in this case the solution depends weakly on the assumed value of $\alpha_{\text{OX}}$.

6.3. Narrow components in the range $-9600 < v < -7000$ km s$^{-1}$

From the C IV profiles (see Fig. 9), it is apparent that this velocity range is dominated by absorptions from individual clouds superposed on a continuous absorption. It is difficult to disentangle both contributions. The narrow C IV systems have small H I optical depth. This is characteristic of systems associated with the quasar.

It is interesting to note on Fig. 9 that the residual flux of O VI$\lambda 1037$ is very small and narrow components are barely visible. This indicates that the continuous gas-component is of higher ionization than the other components in the flow. Absorption due to Si IV is not detected over this velocity range. Thus, the systems are similar to the high-ionization systems discussed in Sect. 5.

6.4. Complex centered at $v \sim -7000$ km s$^{-1}$

As can be seen in Fig. 13, there are at least 10 distinct components (marked with dashed lines) in the C IV profile of this complex. The two strong Lyman-α lines at $\sim -6800$ and $-7100$ km s$^{-1}$ are most probably due to intervening systems. The line at $v = -6800$ km s$^{-1}$ ($z_{\text{abs}} = 3.8018$) is indeed associated with the five weak and narrow C IV and Si IV components with the largest velocities ($> -6850$ km s$^{-1}$).

The other C IV components have strong associated N V absorption with $N(\text{N V}) > N(\text{Si IV})$, typical of associated systems. The non similarity of the N VI$\lambda 1238$ and N VI$\lambda 1242$ profiles indicates that there is some blending. As noted before, the expected position of Lyman-α from the two high-ionization systems at $z_{\text{abs}} \sim 3.90$, discussed in Sect. 5, coincides with N VI$\lambda 1242$ in this system. Moreover, the N VI$\lambda 1242$ line of the system at $v = -8120$ km s$^{-1}$ coincides with the blue wing of the N VI$\lambda 1238$ absorption. The strong absorption in the N VI$\lambda 1242$ profile at $v = -6990$ km s$^{-1}$ is most certainly Lyman-α at $z_{\text{abs}} = 3.904$ with possible N V but no O VI associated absorption.

From the N VI$\lambda 1238$ profile it is clear that the gas producing the N V absorption covers more than 80% of the background source. Fitting of the unblended C IV and Si IV doublets results in covering factors in the range 0.8–0.9±0.1. It is clear from Fig. 14 that the apparent optical depth of H I in the range $-7050 < v < -6900$ km s$^{-1}$ is much smaller than the apparent optical depth of C IV and N V. This suggests that these systems are very similar to the systems discussed in Sect. 5.
6.5. The velocity range \(-6000 < v < -4000\) km s\(^{-1}\)

The absorption profiles in the velocity range considered here is mainly due to broad lines (see Fig. 14). The component at \(v = -5350\) km s\(^{-1}\) is defined by C \(\text{iv}\) \(\lambda 1548\), N \(\text{v}\) and O \(\text{v}\) absorptions. The width of the absorptions is consistent with the definition of “mini-BAL”. It can be seen on Fig. 13 that the optical depth increases dramatically from H \(\text{ii}\) to O \(\text{v}\) (note the weak but significant residual in O \(\text{v}\)\(\lambda 1037\)). This clearly suggests that \(N(\text{O}\text{v}) \gg N(\text{C}\text{iv})\) and that the ionization of this system is very high.

The component at \(v = -4700\) km s\(^{-1}\) is defined by C \(\text{iv}\), Si \(\text{iv}\), N \(\text{v}\) and O \(\text{v}\) absorptions. The two lines of the C \(\text{iv}\) doublet are partially blended. The width of the lines is \(\sim 1500\) km s\(^{-1}\). The Si \(\text{iv}\) \(\lambda 1393\) profile has a width of \(\sim 450\) km s\(^{-1}\). The Si \(\text{iv}\) \(\lambda 1402\) line is blended with the C \(\text{iv}\) \(\lambda 1548\) from \(z_{\text{abs}} = 3.3776\). As the latter intervening system is itself heavily blended, unique profile decomposition is not possible and it is difficult to remove the C \(\text{iv}\) contribution to the broad Si \(\text{iv}\) \(\lambda 1402\) profile. The important observation is that the residual intensities of O \(\text{v}\) \(\lambda 1031\), O \(\text{v}\) \(\lambda 1037\) and N \(\text{v}\) \(\lambda 1238\) are larger than that derived for the component at \(v = -5300\) km s\(^{-1}\) while it is the opposite for the C \(\text{iv}\) residual intensity. This probably indicates that this system is of lower ionization compared to the “mini-BAL” at \(z_{\text{abs}} = -5300\) km s\(^{-1}\).

7. Line-locking

Several mechanisms have been proposed to explain the acceleration of BAL winds (see a review by de Kool 1997). One of the signatures of acceleration dominated by line radiation pressure is the presence of line-locking (e.g. Q 1303+308 in Foltz et al. 1987; NGC 5548 in Srianand 2000). We searched the spectrum of APM 08279+5255 for such signatures in the C \(\text{iv}\) wavelength range. We note that some of the velocity separations between the “mini-BALS” are close to the Si \(\text{iv}\) and O \(\text{v}\) doublet splittings. However as the individual lines are broad, the probability of such occurrence by chance is high. More striking is that most of the narrow C \(\text{iv}\) systems have a “companion” system with a velocity difference corresponding to the velocity splitting of the Si \(\text{iv}\), N \(\text{v}\) or O \(\text{v}\) doublets with line centroids coinciding within 5 km s\(^{-1}\). The maximum number of matchings occurs at the velocity separation of the O \(\text{v}\) doublet as expected for a high-ionization system. As an illustration we show in Fig. 15 the components with velocity separations equal to the O \(\text{v}\), N \(\text{v}\) and Si \(\text{iv}\) doublet separations. We believe that the data are indicative of the presence of “line-locking”.

8. Summary

8.1. Low-ionization systems

Two of the narrow absorption systems (at \(z_{\text{abs}} = 3.8931\) and \(z_{\text{abs}} = 3.9135\)), show absorptions from singly ionized species (C \(\text{ii}\), Si \(\text{ii}\), Al \(\text{ii}\)) whereas absorptions from N \(\text{v}\) and O \(\text{v}\) are weak or absent. Absorptions from excited fine structure levels of C \(\text{ii}\) (excitation energy corresponding to 156\(\mu\)m) and

Fig. 14. Absorptions in the velocity range \(-5700 < v < -4200\) km s\(^{-1}\). The zero of the velocity scale is taken at \(z = 3.911\). The vertical dotted lines are drawn for illustrative purpose at velocities discussed in the text.

Fig. 15. Velocity separations of narrow absorption lines in the BAL outflow. The solid line is the observed C \(\text{iv}\) profile. The dotted line is the C \(\text{iv}\) profile shifted by different doublet splitting: N \(\text{v}\), Si \(\text{iv}\) and O \(\text{v}\) for the upper, middle and lower panel respectively. The vertical dashed lines indicate the places where the centroids of lines match within 5 km s\(^{-1}\).
Si ii (excitation energy corresponding to 34 μm) are detected at $z_{\text{abs}} = 3.8931$. The relative column densities are consistent with the shape of the IR spectrum of APM 08279+5255. Together with the low-ionization level of the system, this favors a picture where the cloud is closer to the IR source than to the UV source. This supports the idea that the extension of the IR source is larger than $\sim 200$ pc. Alternatively, if the excitation is due to collisions, the electronic density must be larger than 100 cm$^{-3}$. The dimensions of the cloud along the line-of-sight is of the order of 0.006 pc and $\sim 50\sqrt{k}$ times larger in the perpendicular direction in order for the covering factor to be $\sim 97\%$ ($k$ is the amplification factor and could be as large as 100). Excited fine-structure lines are not detected in the $z_{\text{abs}} = 3.9135$ system. This suggests that the cloud is farther away from the QSO compared to the $z_{\text{abs}} = 3.8931$ cloud. Using photo-ionization models with and without attenuation by associated systems acting as a screen between the QSO and the gas, it is shown that abundances are $Z \sim Z_\odot$ and 0.01 $Z_\odot$ at $z_{\text{abs}} = 3.8931$ and 3.9135 respectively. All this suggests that whereas the $z_{\text{abs}} = 3.8931$ system is probably located within 200 pc from the QSO and ejected at a velocity larger than 1000 km s$^{-1}$, the $z_{\text{abs}} = 3.9135$ system must be farther away and part of the host-galaxy.

Aluminum could be over-abundant with respect to silicon and carbon at least by a factor of two and five at $z_{\text{abs}} = 3.9131$ and 3.9135 respectively. Such enrichment has already been observed by Ganguly et al. (1998) in a system with a velocity separation of 10000 km s$^{-1}$ with respect to Q1222+228. It is well established that in Galactic halo stars and field dwarfs the odd-Z elements (Na, Al, Cl, P, Mn and Co) have metallicities relative to iron smaller than solar by about a factor of 3 for iron metallicities in the range $-3.0 \leq [\text{Fe/H}] \leq -1.0$ (Timmes et al. 1995). Conversely, $\alpha$-chain elements (O, Ne, Mg, Si, S, Ar, Ca and Ti) generally have metallicities relative to iron larger than solar by about a factor of three for $[\text{Fe/H}] \leq -1.0$. The aluminum and silicon metallicities measured in damped Lyman-$\alpha$ systems follow these trends (Lu et al. 1996). In rapid star-formation models, massive star formation is favored and leads to high enrichment of aluminum and silicon with respect to carbon and nitrogen (Ferland et al. 1996). But [Si/H] is always larger than [Al/H]. Large [Al/Fe] ratios are observed in bright giant stars in mildly metal-poor globular clusters (Ivans 1999). Various correlations between different element abundances suggest that the abundance pattern is most likely due to very deep mixing and proton-capture nucleosynthesis (see Langer et al. 1997 for a review). However, although [Al/Si] is found larger than solar, the excess is quite small (< 0.2 dex) and indeed much smaller than the factor 20 we observe in the $z_{\text{abs}} = 3.9135$ system.

Enrichment of aluminum with respect to silicon is found in the ejecta of classical novae (Andrea et al. 1994; Gehrz et al. 1998). Therefore, the over enrichment of odd nucleus could be explained if the absorption is produced by individual novae shells (Shields 1996). However, novae shells invariably produce very high metal enrichment and high values of [N/C] compared to solar (Petitjean et al. 1990; Andrea et al. 1994), which conflict with the present observations.

### 8.2. High-ionization systems

The high-ionization associated systems at $z_{\text{abs}} = 3.90–3.917$ (redshifts very close or even larger than the assumed intrinsic redshift, $z_{\text{em}} = 3.91$, see Fig. 8) have been shown to have metallicities larger than solar for a Mathews & Ferland ionization spectrum. At this redshift, the maximum life-time allowed by the $\Omega = 1$ cosmology is 0.8 Gyr, suggesting that rapid star formation occurs. We note that the relatively low N v to C iv and O vi column density ratios could be at odd with the standard rapid star-formation models discussed in the literature which predict larger values (Hamann & Ferland 1993; Matteucci & Padovani 1993). However it is known that BALQSOs are X-ray quiet with optical to X-ray spectral index $\alpha_{\text{OX}} \geq 1.9$ (Green & Mathur 1996) when the Mathews & Ferland spectrum corresponds to $\alpha_{\text{OX}} = 1.40$. If the cloud is ionized by a spectrum with $\alpha_{\text{OX}} \geq 1.9$, observations are consistent with metallicities of the order of solar or slightly smaller.

The broad C iv absorption profile has a complex structure. It shows mini-BAL absorptions (of width $\lesssim 1000$ km s$^{-1}$) and narrow components superposed on a continuous absorption of smaller optical depth. There is a tendency for mini-BALs to have different covering factors for different species. Again, this could be due to ionization structure of the BLR or due to ionization gradients in the flow. It is shown that the covering factors of a few of these absorbing clouds, which are well detached from the corresponding broad emission line profiles, are most probably due to the cloud not covering the three images of the lensed quasar. If true, this would put strong constraints on the dimensions of the clouds. HST spectroscopic observations of the three images are needed to confirm these findings. The continuous absorption is much stronger in O vi indicating that the diffuse component is highly ionized compared to the other components in the flow. This suggests that the absorption structures are due to density inhomogeneities within the flow.

The H i column density in the “mini-BAL” is small suggesting large metallicities as is commonly found in associated narrow as well as broad absorption systems. However, there is no absorption from Al iii and P v contrary to what is seen in some of the BAL systems. Indeed, Shields (1997) derived overabundance of aluminum compared to silicon, [Al/Si] = 6[Al/Si]$_\odot$, in the BAL outflows of Q1101+091, Q1231+1325 and Q1331-0108, using photo-ionization models with a Mathews & Ferland (1987) spectrum and ionization parameters in the range $-1.5 < \log U \leq 1.0$. He also noted that there are indications for [Al/Si] being several times larger than solar in the BLR of some QSOs. The Al iii to Si iv optical depth ratio is less than 0.10 in the mini-BALs seen in the spectrum of APM 08279+5255. As the above ratio depends only weakly on the ionization parameter for $\log U \geq -0.50$ (Hamann 1997), we can use a simple scaling of the analysis of Shields (1997) to derive that [Al/Si] = 2 [Al/Si]$_\odot$.

Finally we tentatively identify narrow components within the BAL-flow which have velocity separations very close (within 5 km s$^{-1}$) to the O vi, N v and Si iv doublet splittings. This strongly suggests the existence of “line-locking” and
points towards radiative acceleration as an important process in driving the outflow.

Acknowledgements. We would like to thank the team headed by Sara L. Ellison to have made this beautiful data available for general public use. We gratefully acknowledge support from the Indo-French Centre for the Promotion of Advanced Research (Centre Franco-Indien pour la Promotion de la Recherche Avancée) under contract No. 1710-1.
