ABSTRACT Lipase produced by Aspergillus is widely known and used in many industrial sectors. In a previous study, three lipolytic filamentous fungi were isolated from Kendari (Southeast Sulawesi, Indonesia) landfill soil and identified as Aspergillus niger KE1, Aspergillus terreus KC1, and Aspergillus fumigatus KE6. However, the optimization of these isolates has not been reported. In this study, statistical optimization was selected because it is more effective, efficient, economical, and robust in achieving results, and the possibility of analyzing the interaction effects among factors. Three lipolytic isolates were screened in the initial medium to obtain the highest lipolytic isolate, which was used in the medium optimization process. Optimization was performed using the series experimental design of Taguchi and RSM. Optimization successfully obtained the optimum medium with the reduction of the medium component from the previously reported medium. Aspergillus niger KE1 was the selected isolate with the highest lipase productivity after 72 h in the initial medium. The significant factors affecting lipase production were peptone, olive oil, glucose, and MgSO$_4$7H$_2$O. The model equation obtained was $Y = 1043 - 228A + 300B - 19803C + 99A^2 + 5720B^2 + 292855C^2 - 979AB - 6563AC - 5600B^2C$. This model successfully predicted the lipase productivity with an $R^2$ of 96.9%. The optimized medium was composed of 2% peptone, 0.1% olive oil, 0.5% glucose, and 0.075% MgSO$_4$7H$_2$O. Using the medium, lipase productivity increases 4.7-fold. Our results suggest that A. niger KE1 is a potential lipase source which catalyses the esterification reaction. Further research is needed to purify and characterize the enzyme of this isolate.

1. INTRODUCTION

Lipases (triacylglycerol hydrolase EC 3.1.1.3) catalyse the hydrolysis of triglycerides into fatty acids and glycerol. The enzyme also catalyses the synthesis of esters through transesterification, which is important in biodiesel production (Chen et al. 2011). The most widely applied lipases are produced from microorganisms due to their thermal stability, pH stability, substrate specificity, and activity in organic solvents (Hasan et al. 2009; Costa and Peralta 1999). Filamentous fungi are considered as a potential source of lipase (Falony et al. 2006; Dutra et al. 2008; Thakur 2012). Some advantages of using the filamentous fungi as extracellular lipase producers are their capability to utilize agricultural waste products as a source of nutrients, their ability to produce lipase in solid or broth media, and the simpler separation method of fungal mycelium from the produced enzyme (Sharma et al. 2016).

Aspergillus has been known as the lipase producer that is suitable to be used in many industrial sectors. A previous study by Yanti et al. (2019) obtained three lipolytic filamentous fungi from this genus, namely Aspergillus niger KE1, Aspergillus terreus KC1, and Aspergillus fumigatus KE6, isolated from Kendari landfill soil. These filamentous fungi were the selected lipolytic isolates according to qualitative screening using the rhodamine B agar method. However, the ability of these isolates in producing lipase quantitatively and their optimization is unknown.

Most extracellular lipase production is determined by the composition of the production medium, which is essential to supply nutrients for the microorganisms. Hence, medium composition is selected as a parameter in the optimization process. Furthermore, in the optimization process, the more factors used the greater the number of experiments needed. Therefore, a statistical method is needed to design these experimental processes. Taguchi and response surface methodology (RSM) are two statistical methods that are widely used to replace the conventional approach, such as one factor at a time (Subramonian et al. 2014). Taguchi is used to find the significant factor affecting experimental response(s), while RSM is used to optimize, to find the interaction between the significant factor, and to build the equation model for predicting the optimum response. Some studies have looked at the optimization of lipase production statistically, such as the optimization of the growth condition using FFD and RSM designs (Malillas et al. 2013), and the optimization of an oil source using the RSM design (Oliveira et al. 2017), but there are few reports concerning the medium optimization of lipase production by lipolytic filamentous fungi, statistically, using the series experimental design of Taguchi and RSM. In the present work, the screening of the highest lipase-producing lipoly-
tic filamentous fungi was firstly performed, some significant factors were selected using the Taguchi design, and these significant factors were further optimized using the RSM design.

2. MATERIALS AND METHODS

2.1 Materials

2.1.1 Microbial growth medium

Olive oil was obtained from a local market (Yogyakarta, Indonesia). Potato dextrose agar (HiMedia), peptone (Oxoid), glucose (Merck), KCl (JT Beaker), K2HPO4 (JT Beaker), and MgSO4·7H2O (BDH) were purchased at analytical grade from chemical suppliers in Indonesia.

2.1.2 Chemicals for lipase assay

Ethanol (Merck), oleic acid (Merck), isooctane (Merck), pyridine (Merck), and copper (II) acetate monohydrate (Merck) were purchased at analytical grade from chemical suppliers in Indonesia.

2.1.3 Microorganism and culture condition

Three lipolytic filamentous fungi isolated from Kendari landfill soil in Southeast Sulawesi, Indonesia: A. niger KE1, A. terreus KE1, and A. fumigatus KE6. These isolates were provided by the Laboratory of Microbiology, Universitas Halu Oleo, Indonesia. Pure isolates were kept in potato dextrose agar medium (PDA).

2.2 Methods

2.2.1 Screening of the highest lipase-producing filamentous fungi

Screening was carried out by growing isolates in the lipase production initial medium based on a previous study (Adham and Ahmed 2009). The medium contained 3% (w/v) peptone, 0.05% (w/v) MgSO4, 0.05% (w/v) KCl, 0.2% (w/v) K2HPO4, 0.5% (v/v) olive oil, and 0.5% (w/v) glucose were placed in 250 mL Erlenmeyer flasks. The flasks were inoculated with spore suspension containing 106 spore/ml from a 5-day-old culture grown on PDA and incubated at 30°C with 100 rpm agitation. The culture was harvested every 24 h for 120 h to determine the best time of lipase production of each isolate. All experiments were performed in triplicate. One selected isolate with the highest lipase productivity would be used in the medium optimization process.

2.2.2 Experimental design for medium optimization

Screening of significant factors using Taguchi design. An L27 orthogonal array was used to determine which factors were significant for lipase production. The factors and their levels are shown in Table 1. The experiment was performed in 250 mL shake flasks with 50 mL medium and incubated at 30°C in a shaker (100 rpm) for 72 h. Lipase productivity was measured after 72 h. All experiments were performed in triplicate.

Optimization of significant factors using Box-Behnken design. The significant factors were optimized using RSM. A Box-Behnken design with three factors and three levels was used for fitting a second-order response surface. The experiment was performed in 250 mL shake flasks with 50 mL medium and incubated at 30°C in a shaker (100 rpm) for 72 h. Lipase productivity was measured after 72 h. All experiments were performed in triplicate.

2.2.3 Lipase assay and productivity measurement

The filamentous fungi biomass was harvested from 50 mL medium by paper filtration method and dried in an oven at 70°C for 24 h. The weight of the biomass was measured in grams. The extracellular lipase was estimated according to the lipase activity in the supernant. Lipase activity was determined by incubating 100 μL filtrate with 1 mL isooctane containing 0.25 M oleic acid and 0.25 M ethanol for 20 min at 30°C. The amount of oleic acid at 0 min and after 20 min was determined using the cupric-acetate pyridine colorimetric assay (Kwon and Rhee 1986). One unit of activity (U) is defined as the amount of oleic acid (μmol/mL) converted to product per minute. Lipase productivity (U/g) is the ratio of lipase activity (U/mL) and biomass (g/mL).

2.2.4 Data analysis

All data were analyzed statistically at p < 0.05 using SPSS Version 16 and Minitab Version 17. SPSS was used to perform the analysis of variance, while Minitab was used to analyze the experimental results of the Taguchi design, build the polynomial equation, and predict the optimal parameters of the Box-Behnken design.

3. RESULTS

3.1 Screening of the highest lipase-producing filamentous fungi

Screening of the highest lipase-producing isolate was done quantitatively using the submerged fermentation method. The spore suspension of each isolate was inoculated in the initial medium and was incubated at 30°C with 100 rpm agitation for 120 h. Lipase productivity was measured every 24 h. The lipase productivity of the three lipolytic filamentous fungi is shown in Figure 1. Aspergillus niger KE1 had the highest lipase productivity after 72 h incubation.

| TABLE 1. Factors and levels used in Taguchi design. |
|-------------|-----------|-----------|-----------|
| Factors     | Level 1   | Level 2   | Level 3   |
| Peptone (%) | 1.5       | 3.0       | 4.5       |
| MgSO4·7H2O (%) | 0.0 | 0.05 | 0.1       |
| KCl (%)     | 0.0       | 0.05      | 0.1       |
| K2HPO4 (%)  | 0.0       | 0.2       | 0.4       |
| Olive oil (%) | 0.25 | 0.5 | 0.75       |
| Glucose (%) | 0.0       | 0.5       | 1.0       |
FIGURE 1. Lipase productivity of three lipolytic isolates in initial medium. Incubation was carried out at 30°C with 100 rpm agitation for 120 h.

FIGURE 2. Main effects plot for S/N ratio of lipase productivity; (A) peptone, (B) MgSO$_4$.7H$_2$O, (C) KCl, (D) K$_2$HPO$_4$, (E) olive oil, and (F) glucose.

(331.95±12.76 U/g biomass). Thus, this isolate was used in the medium optimization process.

3.2 Screening of significant factors using Taguchi design
Screening of significant factors was carried out by growing *A. niger* KE1 in various experimental designs of Taguchi. The spore suspension of this isolate was inoculated in each medium and was incubated at 30°C with 100 rpm agitation for 72 h. Lipase productivity was measured after 72 hours of incubation. The result of Taguchi analysis is shown as the main effect plot for the S/N ratio of lipase productivity in Figure 2. Analysis of variance (ANOVA) showed that peptone, olive oil, glucose, MgSO$_4$.7H$_2$O, and the interaction factors of olive oil and glucose were significant with a p value < 0.05 (Table 2). All of these factors can be used in a further optimization process.

3.3 Optimization of significant factors using Box-Behnken design
Optimization of significant factors was done by growing *A. niger* KE1 in various experimental designs of Box-Behnken in RSM. The spore suspension of this isolate was inoculated in each medium and was incubated at 30°C with 100 rpm agitation for 72 h. Lipase productivity was measured after 72 h of incubation. The responses (productivity) for each experiment along with the predicted responses are listed in Table 3. Response surface regression was employed to fit the polynomial equation to the experimental data (Equation 1). The results of the analysis of variance (ANOVA) are summarized in Table 4. The ANOVA showed that the model had a low p value (p < 0.05), indicating that the obtained model was significant. The values of coefficient of determination ($R^2$) was calculated to be 0.969 and showed no lack of fit for the model, so this polynomial equation was reliable and can be used to predict the lipase productivity. The p values of each factor and their interactions were also checked. As shown in Table 4, three linear coefficients of A, B, and C (p < 0.05), two quadratic coefficients of B$^2$ and C$^2$ (p < 0.05), and the interaction factors of B and C (p < 0.05) were significant to the lipase productivity. Generally, the experimental productivity and predicted productivity were similar according to the distribution of the experimental points near to the trendline of the predicted productivity (Figure 3, data from triplicate).

\[
Y = 1043 - 228 A + 300 B - 19803 C + 99 A^2 + 5720 B^2 + 292855 C^2 - 979 A B + 6563 A C - 56338 B C
\]  

where $Y$ is lipase productivity (U/g biomass), $A$ is peptone (%), $B$ is olive oil+glucose (%), and $C$ is MgSO$_4$.7H$_2$O.

3.4 Validation and productivity profile
Validation was performed by repeating the experiment using the optimum medium condition. Spore suspension of the selected isolate was inoculated in this medium and was

### Table 2. ANOVA analysis of each factor using Taguchi design.

| Factors     | DF | SS   | MS    | F-value | P-value |
|-------------|----|------|-------|---------|---------|
| Peptone     | 2  | 60.798 | 30.399 | 10.13   | 0.004   |
| K$_2$HPO$_4$| 2  | 26.598 | 13.299 | 4.43    | 0.042   |
| KCl         | 2  | 15.460 | 7.730  | 2.57    | 0.125   |
| K$_2$HPO$_4$| 2  | 3.867  | 1.933  | 0.64    | 0.546   |
| Olive oil   | 2  | 47.997 | 23.998 | 7.99    | 0.008   |
| Glucose     | 2  | 45.000 | 22.500 | 7.49    | 0.010   |
| Olive oil*Glucose | 4 | 44.114 | 11.029 | 3.67    | 0.043   |
| Error       | 10 | 30.022 | 3.002  |         |         |
| Total       | 26 | 273.855|       |         |         |

![Figure 3](image-url)
incubated at 30°C with 100 rpm agitation for 72 h. Both the experimental and predicted optimum medium condition and optimum productivity are given in Table 5. The experimental value obtained was 1570.34 U/g biomass (mean of triplicate), which was very close to the predicted value of 1595.98 U/g biomass, thus the validation was successful, and the equation was adequate to describe lipase productivity by response surface methodology.

The productivity profile was determined by growing the selected isolate in the initial and optimized media. Each medium was incubated at 30°C at 100 rpm and harvested after 12, 24, 36, 48, 72, 96, 120, 140, and 168 h of incubation. The lipase productivity profile of A. niger KE1 in both initial and optimized media is shown in Figure 4. The optimum lipase productivity was obtained at 72 h. After optimization, it increased 4.7-fold (373%) from the initial medium, as 331.95±12.76 U/g biomass to 1570.34±22.48 U/g biomass.

### 4. DISCUSSION

#### 4.1 Aspergillus niger KE1 as selected lipase-producing fungi

Aspergillus niger has been known as one of the potential lipase-producing filamentous fungi. Many studies reported that this species has great lipase activity, both using the submerged fermentation method and solid-state fermentation with the addition of olive oil theas carbon source and inducer (Thakur 2012; Cihangir and Sarikaya 2004; Sharma et al. 2001). In lipase production, incubation time plays an important role (Ayinla et al. 2017).

As shown in Figure 1, the production of lipase increased steadily and reached its maximum productivity after 72 h by A. niger KE1. Lipase productivity gradually decreased as the incubation time increased further. This result substantiated the work of Mukhtar et al. (2015), which showed a similar pattern of this lipase productivity. Lipase productivity at the initial incubation time was low due to adaptation of the fungus to the new medium. Fungal spores need time for germination and to form hypha. Further incubation time would decrease the metabolic activity due to the depletion of nutrients or accumulation of metabolic toxins, hence the productivity also decreases (Imandi et al. 2010). In addition, Ayinla et al. (2017) stated that a decrease in lipase production may likely be due to the proteases secreted by the fungus, which can cleave and inactivate lipase.

#### 4.2 Significant factors in lipase production from A. niger KE1

As shown in Figure 2 and Table 2, peptone, MgSO₄·7H₂O, olive oil, and glucose were the significant factors for the lipase productivity of A. niger KE1. Those factors have their own important roles in lipase production. Bora and Bora (2012) stated that the release of NH₄+ ions from peptone will stimulate the growth and then can increase the enzyme yield. Other reports also stated that peptone was the best organic nitrogen source for lipase production in Fusarium verticillioides, A. carbonarius IMI 366159, and Trichoderma citrinoviride (Facchinii et al. 2015; Ire and Ike 2014; Akyl and Cihangir 2018).

MgSO₄·7H₂O provides magnesium and sulphur sources. This mineral salt is needed to maintain the osmotic balance and provide the appropriate cationic environment. Magnesium can stabilize the ribosome structure, nucleic acid, enzyme activation in hydrolysis, and phosphate transport, while the reduction of sulphate is used to form cysteine (Hughes and Poole 1989; Griffin 1981).

Many studies have also reported that lipase production increased and gave optimum productivity with the addition of olive oil. Besides serving as a carbon source, olive oil is used as an inducer for lipase production in some fungi, such as Rhizopus homothallicus, A. niger AC-5, A. awamori, A. terreus, and (Rodriguez et al. 2006; Brooks and Asamudo 2011; Xia et al. 2011; Iftikhar et al. 2012; Mahmoud et al. 2015). Although the utilization of olive oil as a carbon source can increase lipase production, many studies also found that some filamentous fungi need the addition of glucose in the medium to maximize their lipase production. Glucose is considered to be important in supporting hypha growth, especially as a component of cell wall building blocks.

Some fungi need the mixture of glucose and olive oil as a carbon source to maximize lipase production; for ex-
After obtaining the significant factors, these factors were not significant in lipase production. Some studies also reported that these factors were suitable to describe the actual condition according to the results of ANOVA (Table 4). The equation had a significant value ($p < 0.05$). This value described that the model inaccuracy was less than 5%. The equation also had no lack of fit ($p > 0.05$), which showed that the estimated response surface could represent the actual condition. Furthermore, the model also had a high coefficient determinant ($R^2$-squared = 96.9%), which indicated that the effect of the factors on the responses was 96%, while the rest were affected by error (Ross 2010). Hence, it can be concluded that the polynomial equation was reliable and can be used to predict the lipase productivity.

The experimental lipase productivity was similar to the predicted productivity. As shown in Figure 3, the distribution of the experimental points near to the trendline of the predicted productivity indicated that the experimental productivity can be accepted (Sridevi et al. 2011).

4.3 Optimization of significant factors

After obtaining the significant factors, these factors were further optimized in RSM, especially using the Box-Behnken design. The polynomial equation (Equation 1) was suitable to describe the actual condition according to the results of ANOVA (Table 4). The equation had a significant

| TABLE 5. Validation of obtained polynomial equation (see Equation 1) from Box-Behnken design. |
|---|---|---|---|---|---|
| Peptone (%) | Olive oil+glucose (%) | MgSO$_4\cdot7$H$_2$O (%) | Predicted | Experimental |
| 2 | 0.1-0.5 | 0.075 | 1595.98 | 1570.34 | 1377.8; 1814.2 | 1310.1; 1881.8 |

Note: CI = confidence interval, PI = predicted interval.
The higher concentration of glucose than olive oil in the optimized medium may likely be due to the utilization of glucose by filamentous fungi to support their growth. Glucose, as a carbon source, is used to enhance hypha growth at the beginning of fermentation (Bindiya and Thiruveedula 2012). Furthermore, Jagtap et al. (2010) found that the increase in lipase production occurred when using the combination of glucose and MgSO$_4$·7H$_2$O as a carbon and mineral salt sources, respectively.

The optimized medium was considered more efficient with the reduction of some insignificant factors for lipase productivity. The optimized medium gave optimum lipase productivity though it only contained some components compared with the previous medium reported by Adham and Ahmed (2009). In addition, the utilization of a small amount of olive oil in the optimized medium can reduce the production cost, so it is useful to be applied in the industrial sector.

5. CONCLUSION

In this study, medium optimization of lipase productivity by A. niger KE1 was carried out by combining Taguchi and RSM designs. Lipase productivity was successfully increased with the reduction of medium components. Peptone, glucose, olive oil, and MgSO$_4$·7H$_2$O were significant factors according to Taguchi analysis and these factors were optimized in RSM. The optimized medium was composed of 2% peptone, 0.5% glucose, 0.1% olive oil, and 0.075% MgSO$_4$·7H$_2$O. Using the optimal condition, lipase productivity was up to 1570.34 U/g biomass, 4.7-fold higher than when using the initial medium. Meanwhile, the adequate polynomial equation predicted the lipase productivity successfully. Our results suggest that A. niger KE1 isolated from Kendari landfill soil is a potential lipase source that catalyses the esterification reaction. Further optimization research using various growth conditions is needed to obtain the optimal growth condition and maximize lipase production. The purification and characterization of the lipase enzyme from this isolate is also needed to determine the enzyme properties.
