Abstract. We compare the light extinction spectra of elongated gold nanoparticles with different shapes (cylinder, spherocylinder and ellipsoid) and sizes of 10 to 100 nm. We argue that the equivalence of the various moments of mass distribution is the natural comparison criterion — rather than the length-to-diameter (aspect) ratio generally used in the literature—and that it leads to better spectral correspondence between the various shapes.

1 Introduction

Over the last two decades, the striking optical properties of noble metal nanoparticles have raised considerable interest. Among the variety of morphologies obtainable by chemical synthesis, “nanorods” (elongated cylindrical or, more commonly, spherocylindrical particles) are some of the most studied, due to their strong longitudinal resonance, which can be tuned by varying their anisotropy.

Silver and gold nanorods were thoroughly studied by UV-Vis-IR spectroscopy. Although numerical simulation techniques are nowadays quite accessible, see, e.g., refs. [1–5], these particles are often modeled as ellipsoids [6–9], since this shape has the great advantage of being amenable to analytical treatment, as briefly discussed in the following; see [10] for a detailed and up-to-date discussion. The scattering problem was solved exactly for a sphere [11] and for an arbitrary spheroid [12], but the expressions are cumbersome. In the Rayleigh (or electrostatic) limit, analytical approximations can be derived for ellipsoids [13]. They are valid for particles much smaller than the wavelength, a condition often fulfilled in practice. More elaborate but still tractable approximations exist, for spheres [14] and spheroids [15–18] beyond the Rayleigh regime.

Unfortunately, the currently prevailing opinion [19–22] is that the ellipsoid model does not accurately describe more realistic shapes, in particular with respect to the longitudinal plasmon resonance (that associated to the longest dimension). The authors reach this conclusion by comparing the position of the longitudinal plasmon peak (LPP) for cylinders, spherocylinders, and prolate spheroids with the same length L and transverse diameter D and hence the same aspect ratio \( R = L/D \) [20]. However, the literature provides no justification for using \( R \) as the comparison parameter.

We consider the relevant criterion for identifying the ellipsoid corresponding to a given particle. In contrast with the established procedure discussed above, we argue that the relevant quantities are the various moments of the mass distribution, leading to an effective aspect ratio \( R_{\text{eff}} \). The spectra of particles with different shapes —cylinder, spherocylinder and ellipsoid— and the same \( R_{\text{eff}} \) agree much better than those for an equal aspect ratio \( R \).

2 Model

The most general description of a mass distribution, for a body or a system of particles, is in terms of its various moments [23]. The first of these are, in increasing tensorial order, \( m \) (the total mass of the system), \( m \mathbf{r}_{\text{CM}} \) (with \( \mathbf{r}_{\text{CM}} \) the center-of-mass vector) and the inertia tensor

\[
I = \int_V d\rho(\mathbf{r}) \left[ (\mathbf{r} - \mathbf{r}_{\text{CM}})^2 I - (\mathbf{r} - \mathbf{r}_{\text{CM}}) \otimes (\mathbf{r} - \mathbf{r}_{\text{CM}}) \right],
\]

where \( V \) is the volume of the body, \( \rho(\mathbf{r}) \) is the local mass density, \( I \) is the unit tensor and \( \otimes \) denotes the outer product. \( I \) is widely used in mechanics, but is also relevant for the interaction of particles with radiation; for instance, the gyration radius \( R_g \) defined as \( m R_g^2 = \frac{1}{2} Tr I \) is extensively used in small-angle scattering techniques [24]. This strategy is also very similar to the traditional way of describing a charge distribution by its total charge, dipole, quadrupole and higher multipolar moments.

In this framework, the ellipsoid equivalent to a given body is the one with the same distribution moments. Geometrically, an ellipsoid is completely defined by three parameters (e.g. the semi-axes) chosen such that the three
All these shapes have azimuthal symmetry around their length, taken as parallel to $z$. We studied three types of particles: cylinders, spherocylinders and prolate ellipsoids, described by their aspect ratio $R = L/D = 5$. For the top two shapes, the superimposed contour represents the equivalent ellipsoid (see text).

The particle position $r_{CM}$ does not influence the absorbance; as to the mass, we will return to it in appendix A.

We performed numerical simulations of the extinction cross-section $Q_{ext}$ of anisotropic gold nanoparticles using the discrete dipole approximation (DDA) code DDS-CAT 7.3 [25,26] with the filtered coupled dipole method [27]. The refractive index of bulk gold $n_{Au}$ is that given by Johnson and Christy [28], with no corrections for boundary dissipation. The ambient medium is water, described by a constant refractive index $n_{water} = 1.33$. The particles are discretized using 90 dipoles along the diameter and 90 · $R$ along the length, where $R$ goes from 1 to 8. The particle radius is 5 nm. The electric field is parallel to the long axis of the particles (along $z$) in order to probe the LPP.

In the transverse configuration (electric field perpendicular to $z$), the spectrum changes very little with the aspect ratio [29]. For randomly oriented particles, e.g. in colloidal solution, the overall spectrum is a superposition of the longitudinal and transverse components, so that a satisfactory description of the longitudinal spectrum ensures that the total spectrum is also correctly described.

To extend the results to larger particle sizes (10 and 20 nm radii) we performed additional simulations using the boundary element method (BEM) [30] as implemented by the MATLAB package MNPBEM [31]. The two methods yield very similar results, as shown in appendix B.

For simplicity, we compare particles with the same radius. Note, however, that identifying the moments in (2) leads to slightly different radii for the ellipsoids as compared to the target particles. We checked that the resulting difference in peak position is negligible.

3 Results

We fitted the extinction spectrum with the sum of a Lorentzian peak and a cubic background to determine the position of the LPP, plotted in fig. 2 for the three shapes, as a function of $R$ (left panel) and $R_{eff}$ (right panel). As reference, we also added the LPP position for ellipsoids in the Rayleigh limit, using the Gans formula (eq. (5.32) in ref. [32]).

As $R$ increases, so does the difference in LPP position between different shapes. When plotted against $R_{eff}$, the agreement is satisfactory description of the longitudinal and transverse components, so that a
4 Comparison with experimental data

We also checked our model against the experimental data measured for gold nanorods with varying aspect ratios in ref. [33]. The mean aspect ratio $R$ and its standard deviation $\sigma_R$ are determined via TEM and are shown in fig. 4 as grey bars versus the sample code. The UV-Vis-IR spectroscopy curves are fitted with an ellipsoid model, yielding the distribution of effective aspect ratio. Its mean $R_{\text{eff}}$ and standard deviation $\sigma_{R_{\text{eff}}}$ are shown as solid diamonds with error bars.

If our model is correct, the $R$ values (open dots) obtained from the experimental $R_{\text{eff}}$ distribution by inverting the middle relation in eq. (3) are the true geometrical ones and should coincide with the TEM results. For most samples this is indeed the case, confirming the improvement. One should however keep in mind that TEM only samples a very small fraction of the particles (those deposited on grids and, among these, only those visible in the images) in contrast with UV-Vis-IR spectroscopy, which averages over all particles contained in a few milliliters of solution. The latter technique should therefore be much more representative of the complete particle distribution.

5 Discussion and conclusion

For ellipsoids in the Rayleigh approximation, the LPP is completely described by a geometrical factor $P_z$. One can then define an equivalent ellipsoid of a particle by fitting its simulated spectrum with the Mie-Gans formula and finding the corresponding $P_z$ [20]. Our approach here is completely different: we find the equivalent ellipsoid of the particle by applying very general principles to its mass distribution and without any consideration of its electrostatic or optical properties.

We conclude that the LPP positions of particles with the same moments of inertia (defined in (2)) are significantly closer than for particles with the same aspect ratio $R$.

In conclusion, when the mass distribution is properly taken into account, the effective ellipsoid approximation...
Fig. 3. Differences between the simulation results and the Rayleigh limit $\Delta \lambda$ as a function of the aspect ratio $R$ (left) and $\Delta \lambda^{\text{eff}}$ as a function of the effective aspect ratio $R^{\text{eff}}$ (right) for particles with $r = 10 \text{ nm}$ (top) and with $r = 20 \text{ nm}$ (bottom). Symbols are as in fig. 2.

Fig. 4. Aspect ratio $R$ determined by transmission electron microscopy (TEM) (grey bars) and effective aspect ratio $R^{\text{eff}}$ measured by UV-Vis-IR spectroscopy (solid diamonds). The geometric aspect ratio for spherocylinders $R$ (open dots) is then extracted from $R^{\text{eff}}$ by inverting eq. (3). The error bars (UV-Vis-IR) and bar height (TEM) indicate the mean $\pm$ standard deviation: $R \pm \sigma_R$ or $R^{\text{eff}} \pm \sigma_{R^{\text{eff}}}$. Based on fig. 5 of ref. [33].

Appendix A. Volume correspondence

The three moments of inertia $I_x$, $I_y$, and $I_z$ completely define the equivalent ellipsoid for a given particle, including its volume $V^{\text{eff}}$ and hence its mass $m^{\text{eff}} = \rho V^{\text{eff}}$. In fig. 5 we show the ratio of $V^{\text{eff}}$ to the volume $V$ of the target particle, for the cylinder and spherocylinder and for aspect ratios from 1 to 8. For reference, we also show the same ratio for ellipsoids having the same aspect ratio $R$ as the target particle.

Clearly, the volumes are much closer when the corresponding ellipsoid is chosen based on the moments of inertia (the discrepancy is below 3%) than based on the aspect ratio (where the discrepancy can reach 33%). This result is noteworthy on two counts: first, because it comforts our choice of the moments of inertia as relevant parameters, and second because the volume must be correctly described for practical applications, e.g. when estimating the particle concentration in solution from the extinction spectrum.

Kostyantyn Slyusarenko is acknowledged for fruitful discussions.
Fig. 5. Ratio of the volume $V_{\text{eff}}$ of the equivalent ellipsoid to the volume $V$ of the target particle (cylinder or spherocylinder), based on identifying the moments of inertia (dotted line) or by using the same aspect ratio (solid line), compared to the exact value of 1 (dashed line).

Fig. 6. Comparison between the DDA and BEM methods. a) LPP position for the three particle shapes, with aspect ratios between 1 and 8, obtained via DDA (symbols) and BEM (lines). b) Comparison between the extinction spectra of spherocylinders, obtained via DDA (symbols) and BEM (lines), for aspect ratios between 2 and 8.

Appendix B. Agreement between the DDA and BEM methods

The DDA method is more time-consuming, so we only used it for the smaller particles (5 nm in radius) and employed the BEM technique for the larger objects. To make sure that the results are compatible, we also ran the BEM simulations for the small particles, with the results shown in fig. 6. The agreement is excellent for the peak position (fig. 6a) as for the longitudinal spectrum (fig. 6b).
