The infinite-layer compound ACuO$_2$ ($A =$ alkaline-earth ions) is regarded as the most suitable material for exploring the fundamental nature of the CuO$_2$ plane because it does not contain a charge-reservoir block, such as a rock-salt or a fluorite like block. We report that superconductivity in the infinite-layer compound Sr$_{0.9}$La$_{0.1}$CuO$_2$ is of a three-dimensional nature, in contrast to the quasi two-dimensional superconducting behavior of all other cuprates. The key observation is that the $c$-axis coherence length is longer than the $c$-axis lattice constant even at zero temperature. This means that the superconducting order parameter of one CuO$_2$ plane overlaps with those of neighboring CuO$_2$ planes all the temperatures below the $T_c$. Among all cuprates, only the infinite-layer superconductor shows such a feature.

The key ingredient of high-temperature superconductors (HTSC) is the CuO$_2$ plane in which superconductivity occurs. Besides the CuO$_2$ plane, the unit cell of HTSC generally contains a charge-reservoir block (CRB) which supplies holes or electrons into the conducting layer. However, the function of the CRB, beyond supplying carriers in the materials, is not yet completely clear. In one respect, the CRB might simply be a spacer between the CuO$_2$ planes. In this case, the block reduces the layer-by-layer coupling. The strong anisotropic nature of HTSC is believed to be a reflection of this weak interlayer coupling. In this context, the infinite-layer compounds ACuO$_2$ ($A =$ alkaline-earth ions) are remarkable, because they do not have a CRB, so the simplicity of their crystal structure may allow in-depth insight into the basic mechanism of cuprate superconductivity. Due to the absence of the CRB, infinite-layer compounds have two notable features. First, the distance from one unit cell to the next is the shortest among all the cuprates. Secondly, as a matter of course, charge carriers can be supplied only from the cations at the A sites. For example, the carrier density of the stoichiometric infinite-layer SrCuO$_2$ is zero. The partial substitution of La$^{+3}$ (or Nd$^{+3}$) for Sr$^{+2}$ results in superconductivity in these compounds. In this case, the carriers are not holes, but electrons.

Recently, we successfully synthesized pure-phase Sr$_{0.9}$La$_{0.1}$CuO$_2$ (Sr(La)-112) with $T_c \simeq 43$ K by using a cubic multi-anvil press. The details of the sample preparation will be given elsewhere. In this work, we measured the reversible magnetization as a function of the temperature and the angle between the $c$ axis and the applied magnetic field. From analysis of the data, we found that the usual HTSC two-dimensional (2D) temperature region of $\xi_c(T) < c$ below $T_c$ did not exist in this compound. This peculiar feature has not been observed in any other high-$T_c$ material. Until now, YBa$_2$Cu$_3$O$_{7-\delta}$ (Y-123) has been known to have the most strong interlayer coupling, but the three-dimensional (3D) temperature region is limited to near $T_c$ only. Previously, it was claimed that the high-$T_c$ superconductivity occurred only on the 2D network of CuO$_2$ planes, since a 3D network did not permit spin or charge fluctuation while a 1D structure did not establish long range order of superconductivity. Hence, our observation of 3D superconductivity in entire region below $T_c$ in Sr(La)-112 provides a new aspect of high-temperature superconductivity.

For the magnetization measurements, we aligned the grains of the sample in commercial epoxy under an external magnetic field of 11 T. Fig. 1 displays the x-ray powder diffraction (XRD) pattern of Sr(La)-112 before and after the grain alignment. The inset of Fig. 1 shows the x-ray rocking curve of the (002) reflection. The full width at half maximum of the reflection is less than 1 degree, which means a good $c$-axis alignment. The aligned sample was approximately 9.5 mm in length and 3 mm in diameter. The reversible magnetization was measured as a function of the temperature and the angle between the $c$ axis and the applied magnetic field by using a superconducting quantum interference device (SQUID) magnetometer (MPMS-XL, Quantum design).

Figure 2 shows the reversible magnetization, $4\pi M(T)$, at fields of $1 \ T \leq H \leq 5 \ T$ parallel to the $c$ axis of the sample. In this figure, the symbols and the lines denote the zero-field-cooled and the field-cooled magnetizations, respectively. In comparison with other cuprates, our data show two interesting features. First, the curves shift to lower temperature as the field increases and are almost parallel to each other. This typical mean-field behavior is consistent with the prediction of the Abrikosov model.
in which the magnetization scales linearly with the magnetic field. Such a feature has never been observed before for any high-$T_c$ cuprate because the mean-field behavior is usually screened by strong thermal fluctuations. Secondly, the rate of decrease of $T_c(H)$ with respect to the field is significantly larger than that of other cuprates, here the superconducting transition temperature, $T_c(H)$, is estimated as the temperature at the point of intersection of a linear extrapolation of $4\pi M(T)$ in the superconducting state with the normal-state base line of $4\pi M = 0$. For instance, at $H = 5$ T, $T_c(H)$ is found to be about 33 K, which corresponds to 0.77$T_c(0)$. Hence, the upper-critical field $H_{c2}(0)$ is expected to be about 20 T, assuming a linear $T_c(H)$. To determine $H_{c2}(0)$ precisely, we apply the Hao-Clem model for reversible magnetization to our data. The details about 2D to 3D occurred at a certain temperature $T^*$ where $\xi_c(T^*) = c/\sqrt{2}$. For moderately anisotropic materials like Y-123, a broader 3D temperature region around $T_c$ was observed due to strong interlayer coupling. However, the 3D region for strongly anisotropic compounds, such as Bi- and TI-based superconductors, was found to be extremely narrow.

Since the unit structure of an infinite-layer superconductor does not contain a CRB, one can expect the coupling between CuO$_2$ planes to be strong. To date, however, no rigorous studies to examine the dimensionality of the compound have been done. With our high-quality samples, we designed experiments to obtain the anisotropy ratio of Sr(La)-122 is about half that of Y-123. This discordance might differentiate Sr(La)-112 from the hole-doped cuprates.

For the cuprate superconductors studied until now, the zero-temperature coherence length along the c axis, $\xi_c(0)$, was found to be much smaller than the unit c-axis length. As the temperature increased toward $T_c$, a dimensional crossover from 2D to 3D occurred at a certain temperature $T^*$ where $\xi_c(T^*) = c/\sqrt{2}$. For moderately anisotropic materials like Y-123, a broader 3D temperature region around $T_c$ was observed due to strong interlayer coupling. However, the 3D region for strongly anisotropic compounds, such as Bi- and TI-based superconductors, was found to be extremely narrow.

In our study, we apply the Hao-Clem model to describe our magnetization data. Since the model is derived from the phenomenological Ginzburg-Landau (GL) theory, our result is justified in the GL framework. However, we judge our result not to be model dependent particularly from the following consideration: The open symbols in the inset of Fig. 2 represent the in-plane magnetic penetration depth, $\lambda_{ab}(T)$, obtained from the dc-magnetic susceptibility, $4\pi\chi_c(T)$, for the low-field region of $H < H_{c1}$. To deduce $\lambda_{ab}(T)$ from the $4\pi\chi_c(T)$ curve, we use the Sloanberg formula, which is not model dependent, but is merely based on the London equations. For comparison, we also plot $\lambda_{ab}(T)$ (filled symbols) from the Hao-Clem analysis in the same figure. We can see that the two curves, indeed, coincide. Thus, we can conclude that the application of the Hao-Clem model in this study does not reduce the generality of our results.

In the inset of Fig. 2, the solid line represents the temperature dependence of the penetration depth assuming the BCS clean limit. The estimated zero-temperature penetration depth, $\lambda_{ab}(0)$, is 147 $\pm$ 6 nm, which is close to $\lambda_{ab}(0) \approx 130$ nm of Y-123. In the framework of the London model, the penetration depth is proportional to $(m^*_{ab}/n_s)^{1/2}$, where $m^*$ and $n_s$ are the electronic effective mass in the $ab$ plane and the charge-carrier density, respectively. According to the empirical Uemura relation, i.e., $T_c \sim n_s/m^*_{ab}$, the $T_c$’s of the two compounds should be nearly the same. However, the $T_c$ of Sr(La)-112 is about half that of Y-123. This discordance might differentiate Sr(La)-112 from the hole-doped cuprates.
the filled-symbol set, the curve shows a plateau behavior at low temperatures and then increases monotonically with temperature. The increase is postulated to originate from the thermal fluctuation effect, as mentioned above. In the open-symbol set, however, no such plateau feature exists. In fact, the London model is known to be suitable for the low-field region of $H \ll H_{c2}$. Since our magnetization data were taken near the transition temperature, the external field of 1 T is regarded as considerably large. Thus, our data set is out of the London region. This is consistent with the $4\pi M(T)$ data in Fig. 2 which lie in the Abrikosov region.

It is quite natural to take the value of the plateau in the filled-symbol set as the real anisotropy ratio. With this value, $\gamma = 9.3 \pm 0.2$, we obtain an out-of-plane coherence length of $\xi = 5.2 \pm 0.3$ Å by using the relationship $\xi = \xi_a \gamma$ and the value of $\xi_a(0)$ from the above analysis. The criterion for 3D superconductivity below $T_c$ is $\xi_a(T) > c/\sqrt{2}$. The value of $\xi_a(0) = 5.4$ Å is considerably larger than the $c/\sqrt{2} \approx 2.4$ Å. This means that the superconducting order parameter of one CuO$_2$ plane overlaps with those of neighboring CuO$_2$ planes even at zero temperature.

Additional evidence for 3D superconductivity can be found from the scaling analysis of the fluctuation-induced magnetization for the high-field region. According to Ullah and Dorsey, the magnetization in the critical region scales with the scaling variable $A(T - T_c(H))/\sqrt{(TH)^n}$, where $A$ is a field and transition temperature-independent coefficient, and $n$ is $2/3$ for a 3D system and $1/2$ for a 2D system. As expected, the magnetization scales excellently with the 3D form. Figure 3 shows $4\pi M(T)/\sqrt{(TH)^n}$ versus the scaling parameter $(T - T_c(H))/\sqrt{(TH)^n}$ with $n = 2/3$. All the data for the different fields collapse onto a single curve. The slope $-dH_{c2}/dT \approx 0.5$ T/K near $T_c$ is obtained from this scaling analysis. This value is fairly consistent with that deduced from the c-axis magnetization analysis.

Our results provide clear evidences for three-dimensional superconductivity, even at zero temperature, in the infinite-layer compound Sr$_{0.9}$La$_{0.1}$CuO$_2$. Here, we deduced the anisotropy ratio $\gamma$ to be about 9 by measuring the angular dependence of the reversible magnetization. This value is somewhat larger than the value of $\gamma \simeq 5$ for Y-123. However, the absence of a CRB in the infinite-layer compound allows the order parameter of one layer to overlap with those of neighboring layers. In addition, we found that the empirical Uemura relation was not applicable to the case of Sr$_{0.9}$La$_{0.1}$CuO$_2$.

FIG. 1. XRD patterns of Sr$_{0.9}$La$_{0.1}$CuO$_2$ before and after the grain alignment. The inset shows x-ray rocking curve of the (002) reflection of aligned sample.

FIG. 2. Temperature dependence of the magnetization, $4\pi M(T)$, measured at applied magnetic fields of $1 \text{T} \leq H \leq 5 \text{T}$ (filled circles, 1 T; open circles, 1.5 T; filled down triangles, 2 T; open down triangles, 2.5 T; filled squares, 3 T; open squares, 3.5 T; filled diamonds, 4 T; open diamonds, 4.5 T; filled up triangles, 5 T). The inset shows the penetration depth, $\lambda_{ab}(T)$, deduced from the Hao-Clem model (filled symbols) and the Shoenberg formula (open symbols). In this figure, the solid line represents the BCS temperature dependence of the penetration depth.

FIG. 3. Angular dependence of the magnetization, $4\pi M(\theta)$, measured at temperatures of $36.5 \text{K} \leq T \leq 40 \text{K}$ and a field of $H = 1 \text{T}$ (filled circles, 36.5 K; open circles, 37 K; filled down triangles, 37.5 K; open down triangles, 38 K; filled squares, 38.5 K; open squares, 39 K; filled diamonds, 39.5 K; open diamonds, 40 K). The $\theta$ denotes the angle between the applied magnetic field and the crystallographic $c$ axis of the sample. The solid lines represent the prediction of the Hao-Clem model. The inset shows the anisotropy ratio $\gamma(T)$ obtained from $4\pi M(\theta)$. The filled and the open symbols are deduced from analyses based on the Hao-Clem and the London models, respectively. The solid lines are just guides for the eyes.

FIG. 4. Scaling of the data of Fig. 1 with the scaling variable $(T - T_c(H))/(TH)^{2/3}$. In this analysis, a linear temperature dependence of $H_{c2}$ near $T_c$ was used assumed, i.e., $-dH_{c2}/dT = 0.47 \text{T/K}$.
