Author’s contribution
The sole author designed, analysed, interpreted and prepared the manuscript.

ABSTRACT

Background: Previous research has shown that the intrinsic reverse (backward) and forward rate constants are larger than the effective or apparent rate constants for the formation and dissociation of an enzyme-substrate complex (ES). It is speculated that such intrinsic rate constants could be larger if an appropriate mathematical equation was adopted for their computation.

Methods: Theoretical, experimental (Bernfeld method), and computational methods.

Objectives: 1) To rederive the equations for calculating the intrinsic rate constants for forward ($k_1$) and reverse (i.e., backward) ($k_2$) reactions; 2) to calculate the intrinsic rate constants; and 3) to show that the probability ($1/g$) (or $\rho_{eq}(r)$) that an enzyme is at a distance from the substrate is a variable.

Results and Discussion: The equations for the determination of $k_2$ and $k_1$ were rederived. Unlike previous findings, the intrinsic (reverse) first order rate, $k_2$ and forward second order rate, $k_1$ were larger than their apparent counterparts, but they were, however, very similar in magnitude. The
1. INTRODUCTION

The issue of intrinsic rate constants has been of interest for many years [1–5]. Both the intrinsic rate constants and the effective rate constants for the association of the enzyme (E) and the substrate (S) or formation of the enzyme-substrate complex (ES) as well as for the dissociation of ES to free enzyme and substrate or product are valuable to both chemical and process engineers. Those experts may reengineer devices that increase apparent or effective rates to attain values closer to intrinsic rates to achieve higher production at a lower cost. The simplest scheme summarising the process is given as: \( E + S \rightarrow ES \rightarrow E + P \). Previous research has shown that the intrinsic reverse and forward rate constants are larger than the effective or apparent rate constants [1]. The intrinsic and apparent 2nd order rate constants are denoted as \( k_1 \) and \( k_0 \), respectively, for the process, \( E + S \rightarrow ES \); the intrinsic and apparent 1st order rate constants are denoted as \( k_1 \) and \( k_0 \), respectively for the process, \( ES \rightarrow E + S \). It is speculated in this research that larger intrinsic rate constants of alpha-amylase can be calculated if the intrinsic forward rate constant, \( k_1 \), is not equal to the diffusion limited rate of encounter, \( k_0 \). Such intrinsic rate constants could be larger than values reported (using \( k_1 = k_0 \)) in earlier research [1]. The concern expressed in the literature is that the undefined term \( g \) cannot be a consistent constant because it is concentration dependent [3]. This view is an offshoot of the view by the author [3] that \( K_C \), the equilibrium constant only for concentrations, is, in fact, not a true constant at all since the intermolecular potential energy, \( U(r) \) will always be concentration dependent. This view seemed to be confirmed by previous results [1], but only on the basis of the application of the diffusion coefficient, which decreases with increasing concentration of the substrate or product and, consequently, the ES. In other words, with approach to terminal velocity (this differs with different concentrations of the substrate), whereupon an effective encounter is to be formed, and ultimately, ES formation, the values of \( g \) may differ. But there is a point in a given time and space for a given substrate concentration range with a specific concentration of the enzyme, where rectilinear motion of the “bullet molecule”, in this case, the much smaller enzyme, moves towards the much larger substrate molecule. Such a point is the specific distance between the enzyme, the bullet, and the target, the substrate, which is heavier and larger than the enzyme.

The magnitude of \( g \) may differ from one substrate concentration range to another. This is not the same as the difference expected on the basis of individual concentration [1]. The implication is that the author’s [2,3] undefined \( g \) (which appears to be the probability that a particle could be at a distance \( r \) from a target if re-expressed in the form of \( 1/g \) because, in the form, \( g = \exp \left( \frac{U(r)}{kT} \right) \), \( g \) must always be greater than one, which is unlikely). Whichever is the case, \( g \) (or its reciprocal) can be taken to be a variable which changes with change in values of rate constants, and it can be shown to be so. A simple analogy is the physical constant known...
as acceleration due to gravity, which is not the same everywhere above the Earth’s surface. Thus, the objectives of this study are as follows: 1) rederive the equations for calculating the intrinsic rate constants for forward (association) \( k_1 \) and reverse (dissociation) \( k_2 \) of E and S and ES respectively; 2) calculate the intrinsic rate constants for the association of E and S, and dissociation of the ES; and 3) show that the probability \( 1/g \) (or \( \rho_{eq}(r) \)) that an enzyme is at a distance from the substrate is a variable constant.

2. THEORY

2.1 Review of Theory

In this review, two approaches, Shurr’s [3] and Vijaykumar et al.’s [5], approaches for the determination of intrinsic rate constants are under consideration. First, is a modified [1] Vijaykumar et al.’s approach [5], given as follows:

\[
k_a(\sigma) = \frac{4 \pi (R_E + R_S)(D_E + D_S) N_A k_{eq}}{4 \pi (R_E + R_S)(D_E + D_S) N_A - k_{eq}}
\]

(1)

where \( k_a(\sigma) \), \( R_E \), \( R_S \), \( D_E \), and \( D_S \) are the 1st order intrinsic rate constant for the dissociation of ES; hydrodynamic radius of the substrate; translational diffusion coefficient of the enzyme; and translational diffusion coefficient of the substrate respectively; \( k_{eq} \) and \( N_A \) are the effective first order rate constants for the dissociation of ES and Avogadro’s number, respectively.

\[
k_a(\sigma) = \frac{4 \pi (R_E + R_S)(D_E + D_S) N_A k_{eq}}{4 \pi (R_E + R_S)(D_E + D_S) N_A - k_{eq}}
\]

(2)

where \( k_a(\sigma) \) and \( k_{eq} \) denote the 2nd order intrinsic and 2nd order effective rate (association) constants, respectively. There is no problem with Equations (1) and (2). Equations (1) and (2) should be carefully examined to avoid a wrong impression of seeing both equations as being the same; one of the nominators in Eq. (1) is an apparent first order rate constant \( (k_{eq}) \) for the dissociation of ES, while in Eq. (2) it is the apparent second order rate constant \( (k_{eq}) \) for the association of E and S.

The modified Shurr’s approach [3] given as:

\[
k_2 = k_b (2 - R/R_b) \quad (\text{Thus } k_2 = f(g))
\]

(3)

where \( k_2 \), \( k_b \), \( R \), and \( R_b \) are the 1st order intrinsic rate constant for the dissociation of ES, the 1st order effective rate constant for the dissociation of ES, the sum of \( R_E \) and \( R_S \), and the intermolecular distance where electrostatic attraction begins. Upon close examination of Eq. (3), one sees that \( g \) or its reciprocal variant does not appear in Eq. (3). Therefore, it may not be needed for the calculation of \( k_2 \) which has already been defined for the process: ES \( \rightarrow \) E + S (A dissociation reaction). As a result, from a mathematical standpoint, \( k_b \) is not a function of \( g \). There may be a reason for the mathematical construct or equation, which is, however, outside the scope of this research.

\[
k_1 = k_t g (2 - R/R_b) \quad (\text{Thus } k_1 = f(g))
\]

(4)

where \( k_1 \), \( k_t \), and \( g \) are the 2nd order intrinsic rate constants for the formation of ES, the 2nd order effective rate constant for the formation of ES, and a dimensionless constant which is needed for the calculation of \( k_1 \), hence it is a function of \( g \); any reason for this, is once again outside the scope of this research. Meanwhile, \( g \) is defined in two ways, viz: In line with Shurr’s [3] definition, it is:

\[
g = \exp. \left( \frac{U(\sigma)}{k_b T} \right)
\]

(5)

The Boltzmann constant and thermodynamic temperature is denoted by \( k_b \) and \( T \) respectively. One needs to understand that Eq. (5) may not be disputed given that the author [3] may have unknown reason for the choice and explanation for the equation. Speculatively, \( g \) may stand for the reciprocal of the real probability function that was not in the first place shown in the literature [3]. Regarding Eqs (4) and (5), it is however, necessary to write that the assumption of equality of \( k_1 \) and \( k_0 \) resulted in the equations as derived in the literature [1]. According to the Vijaykumar et al. [5] method, 1/g (or \( \rho_{eq}(r) \)) is given as:

\[
1/g \text{ (or } \rho_{eq}(r)) = \exp. \left( -\frac{U(\sigma)}{k_b T} \right)
\]

(6)

where \( \rho_{eq}(r) \) is defined as the equilibrium probability that two particles are separated by a distance, \( r \). Equation (6) is to address the fact that the maximum value of \( \rho_{eq}(r) \) is one (1), whereupon \( 1/\rho_{eq}(r) \) (or \( g \)) should always be \( \geq 1 \) as expected if the equation, \( g = \exp. \left( \frac{U(\sigma)}{k_b T} \right) \), is upheld. This implies that \( g \) is no longer taken to be the same as \( \rho_{eq}(r) \) as in the literature [1]. The concern about Eqs (5) and (6) is that there may be confusion if one realises that the maximum intermolecular potential energy is zero in line with the conservative field force principle.
In previous research, it was assumed that \( k_0 \) (\( k_0 \) is the diffusion-limited rate constant), which determines the rate at which the two particles diffuse towards each other [5] may be \( k_1 \) (or at least, \( k_1 \approx k_0 \)); this may be considered not out of place considering the assumption that enzymatic reaction may be diffusion dependent if \( k_0 \approx k_0 \) [3].

According to Shurr [3], diffusion dependence exists if the following conditions are met: a) \([S_1] \approx K_M\) and \(k_0 \approx k_0\), and \(k_0/k_0 \approx K_M\), b) \([S_1] \approx K_M\). Diffusion independence is the case if the following conditions are met: a) \([S_1] \approx K_M\), b) \(k_0 \approx k_0\), c) \(k_1 \approx k_0\), and \(k_0/k_0 \approx K_M\). However, experimental determination of both parameters is needed in order to reach a well-informed decision on whether they are diffusion dependent or not. At the moment, it is not too clear whether or not the dependence on the other relations, such as: \(k_0 \approx k_0\) (or \(k_0/k_0 \approx K_M\)), \([S_1] \approx K_M\), etc [3], is on the basis of the all-or-none principle. Nonetheless, the assumption that \( g \) (1\(g\) as preferred in this research) is a variable constant can be shown as follows.

Recall the following equations (in a modified form) given by Shurr [3].

\[
k_b = \frac{k_0 k_2 \exp \left(-\left(\frac{U(r)}{k_BT}\right)\right)}{f k_1 + k_0/g} \tag{7}
\]
\[
k_f = \frac{k_0 k_1}{f k_1 + k_0/g} \tag{8}
\]

In this research, \( k_1 \) and \( k_0 \) are no longer seen to be equal in order to address the dimensional issue as in previous research [1] in which it was observed that \( k_0 = 4\pi (R_E + R_S)(D_E + D_S) \) in any unit of volume per unit time rather than any unit of volume per mol. per unit time. In the equation, \( R_E \) and \( R_S \) are the hydrodynamic radius of the enzyme and substrate, respectively, and \( D_E \) and \( D_S \) are the corresponding diffusion coefficients. It has, however, been shown that \( g \) is a variable constant in the literature [1], but on the assumption that \( k_1 \) and \( k_0 \) are equal, which also presupposes that they must possess the same valid unit, where \( k_0 \) is now given as \( 4\pi N_A (R_E + R_S)(D_E + D_S) \), where \( N_A \) is the Avogadro’s number (see Levine [6]). Since Eqs (7) and (8) possess the same denominator, the following relations are possible.

\[
\frac{k_0 k_1}{k_f} = \frac{k_0 k_2 \exp \left(-\left(\frac{U(r)}{k_BT}\right)\right)}{k_b} \tag{9}
\]

With the simple algebraic equation, \( 1/g \) (or exp. \( \left(-\left(\frac{U(r)}{k_BT}\right)\right) \)) is given as:

\[
1/g = \frac{k_0 k_1}{k_2 k_f} \tag{10}
\]

As long as \( k_0 \), \( k_1 \), and, by extension, \( k_0 \) and \( k_0 \) are influenced by conditions such as temperature, pH, ionic strength, and the nature of the polymer, as in the case of starch from various sources, \( g \) cannot remain a consistent constant quantity. The rate constants may even vary given different concentration \([S_1]\) ranges of the substrate for the same enzyme concentration, every other condition being constant. However, it is necessary to indicate the assumption by which the assay is undertaken given that where \([S_1] \approx K_M\) (Michaelis-Menten constant), one may be operating on the basis of a reverse quasi-steady-state assumption (or approximation), if in particular, the concentration of the enzyme, \([E]\) is \([S_1]\). It is also possible that \([S_1] \approx [E]\), peculiar to the standard quasi-steady-state (or reactant stationary assumption [7]), even though \( K_M \) may be \([S_1] \approx [E]\) with higher \([E]\). All scenarios are verifiable upon appropriate experimentation so that one can establish either diffusion dependence or independence. In this research, consideration is given to the displacement of the enzyme from what may be referred to as infinity to a point closer to the substrate where there may be mutual electrostatic perturbation. That point is at a distance from the substrate. Their mutual attraction begins with a reduction in (or even an outright absence of) random motion.

A dimensionless factor, \( f \) which was not given any name in the literature [2,3], is re-stated here in modified form, first as:

\[
f = -R(1/g) \int_{r_c}^{R} \frac{dr}{r^2} \tag{11}
\]

where \( R = R_E + R_S \), the reaction radius (regarded, for simplicity, as the sum of the hydrodynamic radii of the enzyme and substrate), and \( R_{c} \) is the equivalent of \( R_0 \) intended to imply that the latter is \( e \) the concentration dependent maximum intermolecular distance, which \( R_c \) stands for. Therefore, Eq. (10) is restated as:

\[
f = \left(1 - \frac{R_c}{R_0}\right)/g \tag{12}
\]

### 2.2 Derivation of Equations for Intrinsic Rate Constants

Since the parameters of the rate constants are linked to translational diffusion and cognate...
diffusion coefficients, it is imperative to make it clear that if reactants remain in their fixed location, there cannot be encounter-complex formation, let alone any form of (bio/physico) chemical reaction. Because of mechanistic issues that are frequently applicable to organic reactions with or without biological catalysts, encounter-complex formation does not always translate to an immediate reaction. This is regardless of whether or not the ultimate variables and kinetic parameters are diffusion dependent. But when encountering complex formations, it must be diffusion dependent.

Substitution of Eq. (12) into Eq. (7) with the elimination of common factors gives, after rearrangement, the following.

\[ k_2 = \frac{k_b k_D}{k_b} \left( \frac{R_0 - R}{R_0} \right) k_1 + k_b \]  

(13)

Meanwhile, Eq. (10) can be rearranged to give an equation for \( k_1 \) and \( k_2 \) as follows:

\[ k_2 = \frac{k_b k_1}{k_2/k_b} \]  

(14a)

\[ k_1 = \frac{k_2 k_D}{g k_b} \]  

(14b)

Substitution of Eq. (14b) into Eq. (13) gives:

\[ k_2 = \frac{k_b k_D}{k_b} \left( \frac{R_0 - R}{R_0} \right) k_2 \frac{k_1}{g k_b} + k_b \]  

(15)

Pulling like terms together gives another equation for \( k_2 \).

\[ k_2 = \frac{k_D k_b}{k_D - (k_b - R) k_1/k_b} \]  

(16a)

Equation (16a) is simplified to:

\[ k_2 = \frac{k_D k_b}{k_D - (k_b - R) k_1/k_b} \]  

(16b)

Unlike in Eq. (14a), Eq. (16b) contains both theoretically determinable parameters (with respect to \( k_D \) and \( R \), for instance) and experimentally determinable parameters.

Rearrangement of Eq. (8) gives:

\[ k_1 = \frac{k_1 (k_2 k_D + k_b / g)}{k_D} \]  

(17)

\[ k_1 = \frac{k_D k_b / g}{k_D - k_1 (1 - k_1 / g) / g} \]  

(18a)

\[ k_1 = \frac{k_D k_b / g}{k_D - k_1 (1 - k_1 / g) / g} \]  

(18b)

In the same vein, Eq. (18b) has both theoretically and experimentally determinable parameters, unlike Eq. (14b). The procedure for the determination of \( R_0 \) can be found in the literature [8] as applied elsewhere [1]; similarly, the determination of \( U(R) \) can be found in the same literature [8]. It needs to be stated that the approach in this research is different since the Einstein-Stokes equation is applicable. All relevant equations are stated in the method section.

3. MATERIALS AND METHODS

3.1 Materials

3.1.1 Chemicals

As in the literature [1], Aspergillus oryzea alpha-amylase (EC 3.2.1.1) and soluble potato starch were purchased from Sigma-Aldrich, USA. Tris 3, 5-dinitrosalicylic acid, maltose, and sodium potassium tartrate tetrahydrate were purchased from Kem light laboratories in Mumbai, India. Hydrochloric acid, sodium hydroxide, and sodium chloride were purchased from BDH Chemical Ltd., Poole, England. Distilled water was purchased from a local market. The molar mass of the enzyme is \( = 52 \) kDa [9].

3.1.2 Equipment

An electronic weighing machine was purchased from Wenser Weighing Scale Limited, and a 721/722 visible spectrophotometer was purchased from Spectrum Instruments, China; a pH meter was purchased from Hanna Instruments, Italy.

3.2 Methods

3.2.1 Preparation of solution of reactants for the assay

The enzyme was assayed according to the Bernfeld method [10] using gelatinised potato starch whose concentration range is 5–10 g/L; the weight average molecular weight of the insoluble potato starch is 6.454exp. (+7) g/mol [11]. The reducing sugar produced upon hydrolysis of the substrate using maltose as a
standard was determined at 540 nm with an extinction coefficient equal to 181 L/mol.cm. A concentration equal to 1 g/100 mL of potato starch was gelatinised at 100 °C for 3 min and subjected to serial dilution after making up for the loss of moisture due to evaporation to give concentrations ranging between 5 and 10 g/L for assays in which [S] \( \gg \) [E], and between 0.3 and 3 g/L for assays in which [E] \( \gg \) [S]. *Aspergillus oryzae* alpha-amylase was concentrated to 0.01 g/100 mL by dissolving 0.01 g of the enzyme (as the stock) in 100 mL of Tris HCl buffer at pH = 7. Tris HCl remains a choice because it is very suitable for the temperature chosen for the assay, apart from its availability. *A. oryzae* is commercially available and it is very suitable with mesophilic stability (stable under moderate temperatures) for the amylolysis of gelatinised starch. Any other enzyme such as *Aspergillus niger* alpha-amylase can be used, but budgetary issues place restrictions on the use of other enzymes for evaluation of equations. The assay of the enzyme, where [S] \( \gg \) [E] and [E] \( \gg \) [S], was carried out with an enzyme concentration \( \exp (-6 \pi n R_u u R / k_BT) \) (24) respectively. Based on conserved field force, the maximum potential energy is zero.

3.2.5 Determination of apparent rate constants

The calculated outcomes of \( \ln ([E]/[E]) \), where \([E]\) is the concentration of free enzyme, can be plotted versus \([S] \) (1 - exp. (-k \( \tau_E \)) ) to yield a slope defined as: \( (k_t + k_0)/K_M \) as described in the literature [13]. The latter is multiplied by the molar mass of maltose for reasons explained elsewhere [13]. In the literature, \( k_t \) is defined as follows [13]:

\[
k_t \tau_E = \ln \frac{1}{1 - \frac{[S]}{[S]} \ln \frac{[S]}{[S]} \ln \frac{[S]}{[S]} \ln \frac{[S]}{[S]}}
\]

(25)

where \( M_{alt} \), \( k_t \) and \( \tau_E \) are the molar mass of malt, the pseudo-first order rate constant for substrate utilisation, and the duration of ES formation in this study. The right hand side of Eq. (24) can be plotted versus values of \( k_t \) calculated by a method described elsewhere [1, 13, 14] to give a slope, being the specific value of \( \tau_E \). As explained in the literature [8], \( \phi \) may be > 1 if there are strong long-range attractive forces in addition to short-range attractive forces. Besides, it is assumed that the enzyme begins with a translational velocity where strong electrostatic attraction begins, but not without the effect of solvent resistance and co-substrate crowding effect. The translational velocity \( u \) is determined in two ways [8] and shown for convenience as follows:

\[
u = 2 \frac{S_{lope-1}}{\tau_2} \left( \frac{S_{lope-1} (R_0 - R) / R_0}{R_0} \right) \] (21)

\[
u = 2 \frac{S_{lope-1}}{\tau_2} / S_{lope-2} \] (22)

The fraction \( (x, x) \) of the total distance covered by an approaching smaller molecule compared to the larger molecule is:

\[
\tau_2 = \frac{\sqrt{M_S/M_E}}{\sqrt{M_S/M_E} + 1}
\]

(23)

3.2.4 The probability that a molecule of an enzyme is at a distance, \( R_0 \), from the substrate

\[
\phi/(\phi_0(t)) = \exp. (-6 \pi n R_u u R / k_BT) \]

(24)
3.3 Statistical Analysis

The mean values of the two determinations were taken.

4. RESULTS AND DISCUSSION

For reasons mentioned earlier in the text, previous research assumed that \( k_0 \) could be equal to \( k_i \). It is framed against the presence or absence of a causative factor(s). Those factors may originate from comparative relationships between independent variables and kinetic variables that this research generated in order to infer the ultimate diffusion dependence or independence. To generate data for needed calculations as evidence-based research (or, better yet, to avoid mystifying the younger ones, undergraduates, and interested individuals outside the field but related fields), a step-by-step approach with graphics (Figs 1, 2a, 2b, 3, and 4) was used. The graphs for the determination of \( v_{max} \) and slope needed for the calculation of the pseudo-first order rate constant for utilisation of substrate, \( k \), are omitted.

In the determination of the duration \( t_{ES} \) of ES formation by the graphical method, there is a need to apply intuition in that a plot of \( \Theta \) versus \( k \) (Fig. (2a)) could be nonlinear if the substrate concentration range includes \( [S_1] < 1 \text{ g/L} \), in particular (though not limited to that) plus \([S_1]\) values \( >K_M \) in line with Michaelian kinetics. This and other issues are discussed below. As a result, not less than six different concentrations of S must be used for the assay so that, from the plot (Figs (1) and (2b), the points (this cannot be < 3 if six different \([S_1]\) were used and < 5 if eight different \([S_1]\) were used) with the highest coefficient of determination, \( R^2 \geq 0.9 \), can be used to determine \( t_{ES} \) as a slope. A time course experiment may be adopted for the determination of \( k \) for different concentrations of the substrate with the same concentration of E instead of calculation in future investigation. Speculatively, this approach, may achieve linearisation of the plot.

As explained in the method section, certain observations were left to be because the simple mathematical models are at this stage subject to evaluation; it is well known that when \([E_1]\) is \( > \) the range of \([S_1]\), a single turnover kinetics [15] or reverse quasi-steady-state assumption kinetics [16] is expected. This means that the initial rates are usually directly proportional to \([S_1]\), in which case the coefficient of determination \( (R^2) \) may be equal to 1. The situation is the same if \([E_1]\) is \( < \) \([S_1]\) as long as the pre-steady-state is under consideration or investigation [16]. It is also speculated that the same scenario is expected if substrate concentrations \( >K_M \) are explored in a short duration of assay; the choice of the range of substrate concentration which covers substrate concentrations that are \( < \) and \( >K_M \) usually produces a hyperbolic relation between the rate and substrate concentration; sometimes, as in this research, it may not be very apparent, but when the experimental variables (the rate or velocity, \( v \) of hydrolysis, for instance) are transformed for other uses as in Figs 1 to 2b, in addition to the effect of outliers, a plot of the transformation

\[
\Theta = \ln \left( \frac{1}{1 - \frac{1}{[S_1]_{max}} \ln \left( \frac{[E_1]}{[E_2]} \right)} \right)
\]

versus the pseudo-first order rate constant for the hydrolysis of the polysaccharide gives a clear-cut nonlinear curve (Fig. 2a). The software is good for formatting the graph, but is not necessary because it is not used for further analysis; it is presented herein to illustrate the issues raised and for the avoidance of doubt. It is pointless conducting further assays. Hence, in this research, the velocities for substrate concentrations which were \( < \) the \( K_M \) value were used to calculate values of “\( \Theta \)” plotted versus \( k \). Although the intended linearisation achieved was not perfect, a coefficient of determination \( \geq 0.9 \) is good enough for this investigation. It is important to realise that this is an experimental data as against simulation.

Having determined the \( t_{ES} \) values for low and high \([E_1]\), the determination of \( k_i \) comes next. This is done as described in the method subsection. The plots (Fig. 3 and Fig. 4) show that the slope for low \([E_1]\) is \( < \) the slope for high \([E_1]\). This means that the expected values of \( k_i \) are different, being lower for low \([E_1]\) than for high \([E_1]\). The reason is that with high \([E_1]\), there is a greater trend toward a single turnover catalytic event [15] than for low \([E_1]\). With excess E, there is always free E in the bulk for the formation of ES.

As shown in Table 1, the kinetic parameters generated from the assay of two different concentrations of the enzyme are different as expected; this should be the case because one meets the condition that satisfies standard quasi-steady-state assumption (sQSSA) [16] or the recently acclaimed reactant stationary assumption (RSA) [7] which is regarded as one
that does not require \([S_T] \) to be \(\geq [E_T] \) to satisfy the condition for the validity of Michaelian kinetics and its cognate kinetic parameters on the basis of the steady-state assumption. The other scenario, however, met the condition that satisfies the criterion for the validity of reverse quasi-steady-state assumption (rQSSA) on the basis of \([S_T] \) being \(\leq [E_T] \). The values of \(k_2 \), \(g \), \(K_M \), \(k_3 \), and \(k_b \) where \([S_T] > [E_T] \) were \(> \) the values where \([S_T] \leq [E_T] \) (Table 1). The value of \(k_1 (7.4054 \text{ exp.}(+6) \text{ L/mol. min}) \) where \([S_T] > [E_T] \) is, however, \(< \) the value \((15.7560 \text{ exp.}(+6) \text{ L/mol. min}) \) where \([S_T] \leq [E_T] \). Where \([S_T] > [E_T] \) and \([S_T] \leq [E_T] \), the values of \(k_3 \) were \(> \) \(k_1 \); the difference was, respectively, \(~ - 3.45 \% \) and \(~ - 17.555 \% \) of \(k_1 \). In the same vein, following the same order, the value of \(k_2 > k_b \); the differences for where \([S_T] > [E_T] \) and \([S_T] \leq [E_T] \) are respectively \(~ 0.044 \% \) and \(~ 0.004 \% \) of \(k_2 \). Unlike the report in the literature [1] in which the intrinsic rate constants \((k_1 = (1.59\pm11.99) \text{ exp.}(+6) \text{ L/mol. min} \) and \(k_2 = (64.69\pm0.49) \text{ exp.}(+4)\text{/min}) \) were \(> \) the corresponding apparent rate constants \((1.42\pm0.20) \text{ exp.}(+6) \text{ L/mol. min} \) and \((58.00\pm10.83) \text{ exp.}(+4)\text{/min}) \), the result in this research compares differently: This is so because the \(k_1 (7.40 \text{ exp.}(+6)/\text{L/mol. min}) \) and \(k_2 (81.34 \text{ exp.}(+4)/\text{min}) \) were respectively, \(< \) and \(> \) their apparent rate constant values given as \(7.66 \text{ exp.}(+6)/\text{L/mol. Min} \) and \(81.34 \text{ exp.}(+4)/\text{min} \) respectively, only where \([E_T] \) is \(\geq [S_T] \). This may be as a result of not equating \(k_D \) with \(k_1 \) in this research.

\[
\phi = \ln \left( \frac{[E_T]M_{alt}[S_T]}{[S_T]} \right)
\]

**Fig. 1.** Determination of the duration, \(t_{ES} \), of ES formation for \([S_T] \geq [E_T] \). \(M_{alt} \), \([E_T] \) and \([S_T] \), and \([E_T] \) are molar mass of maltose, total concentrations of enzyme and substrate, and concentration of free enzyme respectively.

\[
\theta = \ln \left( \frac{[E_T]M_{alt}[S_T]}{[S_T]} \right)
\]

**Fig. 2a.** Plot showing nonlinear curve for the complete substrate concentration range for the determination of \(t_{ES} \). A better coefficient of determination is applicable in the range \(1.2 \rightarrow 3 \text{ g/L} \).

\(\theta \) is defined in Fig 1.
Fig. 2b. Determination of the duration, $t_{ES}$, of ES formation, for $[S_T] \ll [E_T]$. Definition of symbols, are as in Fig 1. The range of $[S_T]$ used for the plot is 1.2 → 3 g/L. The full range, 0.3 → 3 g/L showed poor correlation = 0.8116 ($R^2 = 0.6587$) for what was a hyperbolic curve Fig. is not shown.

Fig. 3. Determination of the 2nd order rate constant for $[S_T] \gg [E_T]$. $[S_T]$, $[E_T]$, $[E_F]$, $t_{ES}$, and $k$ are the total concentrations of the substrate and enzyme respectively, concentration of free enzyme, duration of ES formation, and pseudo-first order rate constant for the utilisation of the substrate.

Fig. 4. Determination of the 2nd order apparent (or effective) rate constant where $[S_T] \ll [E_T]$: Definitions of symbols are as in Fig. 2.
Unlike previous research [1], this study investigated two different concentrations of the same enzyme, Aspergillus oryzae alpha-amylase, to determine the effect of a much higher concentration of enzyme, which is in line with the usual reverse quasi-steady-approximation (rQSSA) requirement or where a single-turnover catalytic cycle is of interest. Thus, on the issue of criteria for either diffusion dependence or independence, the results for \([E] > [S]\) and for \([S] > [E]\) showed that the rate of reaction for both was diffusion dependent since \([S] < K_M\) (Table 1); hence, as Table 2 shows, diffusion independence is not applicable because \([S] > K_M\) is neither \(> K_D\) nor \(\geq K_D\). In both scenarios, there was a case of diffusion independence in a situation in which \(k_3 < k_0\), and consequently, diffusion dependence is not applicable because, \(k_3 \geq k_0\). None of the scenarios gave values of \(k_i\) which are either \(> K_0\) or \(= K_0\), leading to both rates being taken to be diffusion independent; this is also applicable to the ratio, \(k_3/K_0\), which being \(< K_M\) (Table 1) shows that the rates for the scenarios are again diffusion independent; the condition or criterion that \(k_3/K_0 = k_0\) is indeed not satisfied, hence diffusion dependence is not applicable in all scenarios (Table 2) An earlier study [1] discovered that the same enzyme had diffusion-controlled kinetic parameters because \(k_0 > k_3\) and \(K_M > [S]\). This is unlike in this research, in which the same enzyme's kinetic parameters can be ascribed to both diffusion independence because \(k_3 > k_0\) and diffusion dependence because \(K_M > [S]\). This may be as a result of the different conditions of assay, in addition to not assuming the equality of \(k_1\) and \(k_2\) in the derived equations. At the discretion of the investigator, the chosen pH and temperature can be below or above the optimum conditions for maximum catalytic activity. Whatever choice is made, the catalytic activity of the enzyme can be affected. However, the derived equations for \(k_2\) and \(k_3\) without the assumption of \(k_1\) being equal to \(K_0\) could have given rise to larger values of intrinsic rate constants (Table 1).

One of the greatest challenges in any investigation for the determination of the intrinsic rate constant is the determination of the minimum interparticle distance \((R_0)\) for the commencement of mutual electrostatic interaction between the substrate and the...
enzyme. This has been solved as recorded in the literature [8] and applied in recent research [1]. The 2nd challenge is the determination of total interaction energy that has also been solved [8, 17]. As Table 1 shows, the $R_0$ value for $[S_1] > [E_1]$ is > the value for $[S_1] < [E_1]$. This constitutes the basis for describing $g$ and its reciprocal variant as a variable constant, just like the acceleration due to gravity, which is not constant in every location above the Earth’s surface. The effect of different locations above the Earth’s surface is analogous to the effect of different concentration ranges and regimes of the substrate and enzyme. This means that different $g$ and, consequently, different $U (R_0)$ will always exist. Thus, $g$ (or $1/g$) remains a variable constant (not a pseudo-constant), given Eq. (10).

There is no doubt that rate constants, including intrinsic rate constants, are important in research, industry, biological processes etc. So far, fundamental issues which concern the generated kinetic constants, some of which are variable constants, in that they are functions of the concentrations of substrate and enzyme, have been discussed and analysed. Most of them are regular features in kinetic studies, in steady-state and pre-steady-state scenarios [15, 18-20]. However, the intrinsic rate constants seem to be a recent development, with much less attention given to amylolytic enzymes. Some research activities end up as purely theoretical papers [2,3]. This research has given quantitative effect to theoretical input on the problem of intrinsic rate constants. There is a need, however, to add that work is going on in the area of the kinetics of cellulose hydrolysis by cellulases where, in one instance, the apparent processivity was observed to be typically smaller than the intrinsic processivity defined on the basis of a theoretical model using apparent rate constants [21]; this is quite similar to the procedure in this research. In order to understand the role of the catalytic site, the catalytic domain has been modeled as a one-dimensional stochastic "walker" that may only step in the forward direction as governed by an intrinsic rate constant, [22]. The latter is given as [22]:

$$k_c^{(0)} = \nu e^{-\Delta U(g)}$$

(26)

The interest in Eq. (26) cited in the literature is in its attribution to the intrinsic rate constant, the object of this research. There is a need, however, to state that thermal energy ought to be part of the exponent such that the equation takes the form (for probable future application):

$$k_c^{(0)} = \nu e^{-\Delta U(g)/k_B T}$$

(27)

where $\nu$ is some transition frequency and $\Delta U (g)$ is the activation energy in units of $k_B T$ ($k_B$ and $T$ are the Boltzmann constant and thermodynamic temperature, respectively) of the intrinsic potential $U (x)$ at position $g$. The implication is that there must be a way of defining quantitatively the intrinsic rate constant that should be known as the intrinsic catalytic rate constant for the formation of product considering the Arrhenius equation. Of course, this research investigated only the intrinsic reverse and forward rate constants. That constitutes the limit of the scope of this research.

Researchers in recent times are now applying a yet to be significantly understood fractal theory to the determination of total activity coefficient and what the authors [23] refer to as an intrinsic constant as applicable to the hydrolysis of recalcitrant cellulose. How the two parameters were determined with the results is not so clear considering the two different definitions of a constant, $K$, given as: 1) the initial rate coefficient at $t = 0$ and 2) the inherent specific activity on the insoluble substrate. The first definition is connected to the equation [23] given as:

$$k = K t^h$$

(28)

### Table 2. Classification of enzymatic action on the basis of diffusion dependence (Diff-Dep.) and independence (Diff-In-dep.), based on Shurr’s [3] criteria where $[S_1] > [E_1]$ and $[S_1] < [E_1]$

| Criteria for Diff-In-dep. | Results | Diff-dep. | Results |
|---------------------------|---------|-----------|---------|
| $[S_1] > K_M$             | NA      | $[S_1] < K_M$ | NA      |
| $k_f = k_0$               | A       | $k_f = k_0$ | A       |
| $K_0 = K_0$               | A       | $K_f/k_0 = K_M$ | A       |
| $k_f/k_0 = K_M$           | -       | $K_f = k_0$ | NA      |
|                           |         |            |         |

The alphabetic symbols, NA and A, means ‘not applicable’ and ‘applicable’ respectively.
where \( k, t, \) and \( h \) are the specific activity of the enzyme, time, and fractal factor.

The second equation [23] is given as:

\[
P_{\text{tot}} = KE_p t^{(1-h)}
\]

(29)

where \( P_{\text{tot}} \) and \( E_p \) are the total generated product and the productively bound enzyme, respectively. It is hoped that researchers in this and similar fields show interest and come up with better explanations of how the intrinsic rate constant, in particular, can be determined. Indeed, gelatinised insoluble starch is far more soluble than raw starch in relative terms, just as the latter is far more soluble than cellulose. The question that cannot be answered now is whether or not fractal theory and its methods can be applied to the kinetics of gelatinised insoluble starch or raw starch, considering the observation that cellulose digestion shows the same time dependence of the specific activity coefficient as described for fractal systems. Interacting with other scholarly works is important, hence these comments, analysis, and proposition or view, and thus it is instructive to write that there is another comment, analysis, and proposition or view, and it is instructive to write that there is another view about the intrinsic nature or property of enzymes. “The measured kinetics of an enzyme-catalysed reaction in free solution, where the enzyme is solubilised, is generally, termed intrinsic” [24]. This may imply that the apparent rate constants are also intrinsic in contrast to what is referred to as observed kinetics and cognate rate constants or coefficients, as may be applicable.

In the light of emerging interest in intrinsic rate constants in recent times, the position taken in this research is that the kinetics of enzyme catalysed reactions in which the enzyme and substrate are in solution (the homogeneous case) and the enzyme and insoluble substrate are in the reaction mixture (the heterogeneous case) are different from the kinetics of either immobilised enzyme given free substrate, be it either soluble or insoluble or immobilised substrate. Otherwise, the kinetics and cognate rate constants for the immobilised reactants, either the enzyme or substrate, are apparent or observed but may be quantitatively and perhaps qualitatively different from those of the free enzyme or substrate.

While research has shown that the intrinsic Michaelis constant of the immobilised enzyme is very close to that of the enzyme in solution, such a constant for the immobilised enzyme tending towards the value for the enzyme in solution when activity is zero [25] is incomprehensibly unusual going by the definition of Michaelis constant. To be specific, the Michaelis constant is the substrate concentration at half the maximum velocity of catalysis or catalytic activity. In the light of this research, a reference to intrinsic Michaelis constant implies that there are intrinsic reverse, forward, and catalytic rate constant given the steady-state equation of Michaelis constant \((K_M)\) given as: \(K_M = (k_f + k_{cat})/k_1\). However, intrinsic rate constants are typically presented in the theory of diffusion-influenced processes as purely abstract, implicitly known variables [5]. This seems to suggest that they are not directly determined as in this research, in which \(k_2\) and \(k_1\) were calculated by fitting relevant equations to experimental or apparent rate constants. Nonetheless the issue of diffusion [3, 5, 26-28] and rates in general but with occasional emphasis on intrinsic rate constants has been investigated for various reasons, which include modeling of cellular sensing [29], characterisation of enzymes of clinical importance [4], etc. Recently, it has been believed that explicit knowledge of these intrinsic rates is necessary in order to simulate complex biological processes [5]. All of these go to show that the importance of intrinsic rate constants cannot be overemphasised and that there should be a way for the determination of intrinsic catalytic rate constant \((k_{cat})\).

5. CONCLUSION

The equations for the determination of intrinsic reverse (i.e. backward) first order and second order rate constants were re-derived. Unlike previous research findings, the intrinsic reverse first order rate \((k_2)\) and forward second order rate \((k_1)\) constants were higher than their apparent counterparts, but they were, however, very similar in magnitude. The intrinsic rate constants were much higher than previously reported values when enzyme’s (E) total concentration \([E_t]\) was « than substrate’s total concentration \([S_t]\). The \(k_f\) and apparent forward second order rate \((k_1)\) values where \([E_t]\) is > \([S_t]\) are > where \([E_t]\) is < \([S_t]\). Therefore, the magnitude of the second order rate constant is a function of \([E_t]\). The values of \(k_f\) and \(k_2\) where \([E_t]\) « \([S_t]\) and vice-versa were respectively, \(\approx 7.41 \times 10^5 \) M/L mol. min and \(\approx 81.34 \times 10^5 \) M/L mol. min, and \(\approx 15.76 \times 10^5 \) M/L mol. min and \(\approx 58.08 \times 10^5 \) M/L mol. min. The probability \((1/g)\) (or \(r_0(t)\)) that an enzyme is at a distance away from the substrate with the possibility of mutual attraction has been found to
be a variable constant contingent upon the concentration of the components of the reaction mixture and the affinity of the enzyme for the substrate and vice-versa. Future research may attempt to derive an equation for the determination of an intrinsic catalytic rate constant for the formation of a product.

ACKNOWLEDGEMENTS

As usual, the management of the Royal Court Yard Hotel in Agbor, Delta State, Nigeria, provided power to aid in the creation of the text. I'd like to take this chance to express my gratitude to my sister, Rosemary Udema, and my brother, Okechukwu Udema, for their moral support. I also want to express my gratitude to the creators of the online Quillbot.com grammar checker.
