Introduction: The under-drafting Digital Video Broadcasting-Next Generation Handheld (DVB-NGH) standard firstly integrates the multiple-input multiple-output (MIMO) technique in the TV broadcasting aiming at efficiently delivering video services for the mobile terminals in the short future. Current digital TV broadcasting systems widely adopt the single-frequency network (SFN), a network deployment where all transmitters simultaneously send the same signal using same frequency band to enlarge the coverage without requiring extra frequency bands. In order to keep compatibility with SFN, the future broadcasting systems should adopt MIMO coding schemes over adjacent broadcasting cells, namely distributed MIMO coding. Fig. 1 shows the distributed MIMO scenario considered in this work where MIMO coding is carried out not only among the two transmit antennas of the same cell (intra-cell coding) but also over two neighboring cells (inter-cell coding); the receiver equips two antennas forming a 4 × 2 MIMO transmission. Due to the difference between the propagation distances (d1 and d2), the signals coming from different cells has different power, which affects the performance of the distributed MIMO coding.

Some space-time block codes (STBCs) such as 3D code, Jafarkhani code, L2 code, DjABBA code, Biglieri-Hong-Viterbo (BHV) code and Srinath-Rajan code which adapt to this scenario have been proposed in the literatures [1, 2, 3] and references therein. However, all of them are either too complex for practical use or not robust to power imbalance of the two transmitters simultaneously sending the same signal using same frequency network (SFN) broadcasting deployments. The new code outperforms existing STBCs with equivalent decoding complexity and approaches those with much higher complexities.

New proposal for 4 × 2 MIMO transmission: All the aforementioned STBCs form codeword over four channel uses (i.e. T = 4). To reach full-rate, eight information symbols (i.e. Q = 8) should be stacked in a codeword, which will result in high decoding complexity. To reduce the complexity, we propose to encode four information symbols (i.e. Q = 4) over two channel uses (i.e. T = 2). As proved later, this proposal guarantees full code rate while limiting the decoding complexity. Recall that the Golden code possesses high diversity with full rate in a 2 × 2 MIMO transmission. Its encoding matrix is:

$$C_{GC} = \begin{pmatrix} X_1(1) & X_2(1) \\ X_2(1) & X_1(2) \end{pmatrix} = \begin{pmatrix} \alpha & \alpha^3 \\ \alpha^3 & \alpha \end{pmatrix},$$

(1)

where $\alpha = e^{j\pi/3}$, $\bar{\alpha} = e^{-j\pi/3}$, $\alpha^2 = e^{j\pi/3}$. Setting the four elements of the codeword in a vector $x = [X_1(1), X_2(1), X_1(2), X_2(1)]^T$, the encoding can be further expressed by a linear transform (denoted by a generator matrix $G$) to information symbols $s = [s_1, s_2, s_3, s_4]^T$:

$$X = Gs,$$

(2)

where $s = \begin{pmatrix} s_1 & s_2 & s_3 & s_4 \end{pmatrix}^T$, $G = \begin{pmatrix} e^{j\varphi} & e^{j\varphi} & 0 & 0 \\ -e^{j\varphi} & e^{j\varphi} & 0 & 0 \\ 0 & 0 & e^{j\varphi} & e^{j\varphi} \\ 0 & 0 & -e^{j\varphi} & -e^{j\varphi} \end{pmatrix}$.

We know that Alamouti code is the most robust scheme in presence of imbalance of received signal power [1]. With this knowledge and exploiting the property of Golden code, we propose a new STBC:

$$C = \begin{pmatrix} X_1(1) - X_2(2) \\ X_1(2) - X_2(1) \end{pmatrix} = \begin{pmatrix} \alpha(\alpha^2 + \bar{\alpha}^2) - \alpha^3(\alpha^2 + \bar{\alpha}^2) \\ \alpha^3(\alpha^2 + \bar{\alpha}^2) - \alpha(\alpha^2 + \bar{\alpha}^2) \end{pmatrix},$$

(3)

where $(\cdot)^*$ is the complex conjugate. We note that, being different from the 3D code [1] which hierarchically encodes two Golden codewords with an Alamouti structure, the new code arranges one single Golden codeword in a similar manner for the sake of low decoding complexity while keeping the merit of robustness to power imbalance. Since there are only 4 information symbols in one codeword, the space search of the new code using ML decoder is $O(M^4)$. We will highlight some important properties of the proposed code and give concise proofs as follows.

**Property 1 (Full Rate):** The proposed STBC in (1) achieves full rate.

**Proof:** The code rate of the proposed code is $R = Q/T = 2$ which is equal to the number of received antennas $N_r$. Hence the new code is full rate.

**Property 2 (Rank of Codeword Difference Matrix):** The rank of the codeword difference matrix $D = C - \bar{C}$ is always equal to 2 for all pairs of distinct codewords $C$ and $\bar{C}$, $C \neq \bar{C}$.

**Proof:** Suppose two distinct codewords $C$ and $\bar{C}$ are generated from two information symbol groups $s = [s_1, s_2, s_3, s_4]^T$ and $s = [\bar{s}_1, \bar{s}_2, \bar{s}_3, \bar{s}_4]^T$ in which the corresponding symbols $s_j$ and $\bar{s}_j$ are not exactly the same, i.e. $s_j \neq \bar{s}_j$, being nonzero for at least one location $j$. At least one encoded symbol $X_{\bar{m}}(n)$ is different from the corresponding $X_m(n)$, $orall m \neq \bar{m}, n \in \{1, 2\}$. Hence, none of the two columns of matrix $D$ is a zero vector. With this fact and considering that the two columns of matrix $D$ are orthogonal, these two columns are necessarily linearly independent. Therefore, the column rank of the codeword difference matrix $D$ is 2.

**Property 3 (Diversity Gain):** The diversity gain provided by the proposed code is $2N_r$.

**Proof:** The achievable diversity gain of a STBC is $rN_r$ given $N_r$ the number of receive antennas and $r$ the minimum rank of codeword difference matrix over all pairs of distinct codewords $\bar{C}$. With this fact and taking the result of Property 2, it achieves Property 3.

**Property 4 (Coding Gain):** The proposed code achieves a coding gain of $d_{min}$, where $d_{min}$ is the minimum Euclidean distance of the constellation adopted by the information symbols.

**Proof:** The coding gain $d_{min}$ provided by STBC code can be computed as $(\prod_{i=1}^{r} \lambda_i)^{1/r}$, where $\lambda_i$, $i = 1, 2, \ldots, r$, are the nonzero eigenvalues of the codeword distance matrix $D \cdot D^T$. Taking into account the value of $D$ with the proposed code, the two nonzero eigenvalue are $\lambda_1 = \lambda_2 = \sum_{m=1}^{N_r} \sum_{n=1}^{N_r} |X_m(n) - \bar{X}_m(n)|^2$ which is equal to the squared norm the first column of matrix $D$ (denoted by $d$). Considering that the $X$ is linearly coded from $[s_1, s_2, s_3, s_4]^T$, $d$ can be expressed as $d = G(s - \bar{s})$. Its squared norm is equal to $\|d\|^2 = (s - \bar{s})^H G^T G (s - \bar{s}) = |s - \bar{s}|^2$ which is minimized when there is only one information symbol $s_j$ being different from the corresponding $\hat{s}_j$ and these two symbols are the closest to each other among all combinations of constellation points. Therefore, the resulting minimum value of eigenvalues is $d_{min}$ given $d_{min}$ the minimum Euclidean distance of the constellation adopted by the information symbols. Taking into account the minimum rank of the proposed code $r = 2$, the resulting coding gain is equal to $d_{min}^2$.

Low-complexity decoding algorithm: Assuming that the channel remains constant over two time slots, the received signal $y$ can be written as:

$$y = X(1) + W_1(1) + W_2(1) + W_3(1) + W_4(1),$$

(4)
where \( w \sim \mathcal{CN}(0, 2\sigma^2I_k) \) is complex white Gaussian noise vector and \( H \) is the channel matrix. The \((m, n)\)th element of \( H \) is the channel gain from the \( n \)th transmit antenna to the \( m \)th receive antenna, modeled as independent and identically distributed (i.i.d) circular symmetric Gaussian distribution. Dividing the channel matrix into two parts i.e. \( H = [H_1, H_2] \) with \( H_1 \) and \( H_2 \) being the first and last two columns, respectively, and considering that the encoding matrix of the Golden code \( \mathcal{G} \) is block-wise diagonal, the received signal in (4) can be written in block form:

\[
y = [H_1, H_2] \begin{bmatrix} G_1 & 0 \\ 0 & G_2 \end{bmatrix} \begin{bmatrix} u \\ v \end{bmatrix} + w = F_1u + F_2v + w,
\]

where \( u = [s_1, s_2]^T \), \( v = [s_3, s_4]^T \), \( F_j = H_jG_j \) with \( j \in \{1, 2\} \). The likelihood function of information symbols \( u \) and \( v \) provided is given by (6):

\[
p(y|u, v) \propto \exp\left(-\frac{1}{2\sigma^2}\|y - F_1u - F_2v\|^2\right)
\]

Conclusion: We have proposed a novel STBC for the next generation mobile broadcasting using distributed MIMO. The new code provides efficient performance with a large range of incoming signal power imbalance without requiring high decoding complexity. It can be concluded that the new code achieves the best complexity-performance trade-off in the distributed MIMO broadcasting scenarios.
