ABSTRACT

Short gamma-ray bursts (SGRBs) observed by *Swift* are potentially revealing the first insight into cataclysmic compact object mergers. To ultimately acquire a fundamental understanding of these events requires pan-spectral observations and knowledge of their spatial distribution to differentiate between proposed progenitor populations. Up to April 2012 there are only some 30% of SGRBs with reasonably firm redshifts, and this sample is highly biased by the limited sensitivity of *Swift* to detect SGRBs. We account for the dominant biases to calculate a realistic SGRB rate density out to $z \approx 0.5$ using the *Swift* sample of peak fluxes, redshifts, and those SGRBs with a beaming angle constraint from X-ray/optical observations. We find an SGRB lower rate density of $8^{+5}_{-3} \text{Gpc}^{-3} \text{yr}^{-1}$ (assuming isotropic emission), and a beaming corrected upper limit of $1100^{+700}_{-470} \text{Gpc}^{-3} \text{yr}^{-1}$. Assuming a significant fraction of binary neutron star mergers produce SGRBs, we calculate lower and upper detection rate limits of $(1-180) \text{yr}^{-1}$ by an aLIGO and Virgo coincidence search. Our detection rate is similar to the lower and realistic rates inferred from extrapolations using Galactic pulsar observations and population synthesis.

Key words: stars – gamma-ray burst: individual – gravitational waves – techniques: miscellaneous – stars: neutron

1 INTRODUCTION

It is generally accepted that ‘long’ ($T_{90} > 2 \text{ s}$) gamma-ray bursts (GRBs) are linked to the core collapse of massive stars (collapsars) (Woosley 1993; Paczynski 1998; MacFadyen & Woosley 1999). For several cases, the GRBs are firmly associated with Type Ib/c supernovae (e.g. Hjorth et al. 2003; Stanek et al. 2003). This strongly suggests that they are linked to the end point of massive stellar evolution. In contrast ‘short’ ($T_{90} < 2 \text{ s}$) gamma-ray bursts (SGRBs) have a less certain origin.

The first breakthrough to understanding the nature of SGRBs was made in 2005 after the launch of the NASA *Swift* satellite (Gehrels et al. 2004). Prompt localizations and deep afterglow searches yielded the first redshifts and investigations of their progenitor environments. By late 2011, about three dozen SGRBs had been localized by *Swift*. Among them, about 50% have optical detections and about one third have redshift determinations based on host galaxy spectroscopy.

Binary neutron star mergers (NS-NS) or neutron star–black hole (NS-BH) mergers are favoured as the progenitors for SGRBs, based on the association of some SGRBs with an older stellar population, as compared to long GRBs. Evidence for the origin of SGRBs in the final merger stage comes from the host galaxy types (e.g. Lee Ramirez-Ruiz & Granot 2003; Zheng & Ramirez-Ruiz 2007). Kicks imparted to NSs at birth will produce velocities of several hundred $\text{km s}^{-1}$, implying that binary inspiraling systems may occur far from their site of origin. Fong, Berger

$^1$ $T_{90}$ is the duration in which the cumulative counts are from 5% to 95% above background.
& Fox (2010) using Hubble Space Telescope observations to measure SGRB-galaxy offsets, find the offset distribution compares favourably with the predicted distribution for NS-NS binaries.

Despite this progress, unambiguous identification of burst types continues to be a problem. The various ambiguities have motivated several authors to re-define different classes of GRBs via a number of properties including: spectral features, associated supernova, stellar population, host galaxy, location in the host galaxy and progenitor type (Zhang et al. 2007). Some authors also suggest a third intermediate population of bursts based on the existing $T_{90}$ scheme (Horváth et al. 2008), with a lower than average peak-flux distribution (Veres et al. 2010).

Furthermore, work by Bromberg et al. (2012) shows that categorizing bursts as SGRBs based on $T_{90}$ is satellite dependent. They find that $2 \, s > T_{90}$ is statistically reasonable for BATSE bursts, but not accurate for Swift bursts. To quantify this uncertainty, for a 0.7-s burst they show that there is an equal probability of its being either long or short. We account for this uncertainty, and its effect on the intrinsic SGRB rate, we scale our SGRB rate estimates using a refinement of these probabilities that incorporates a power law fit to the bursts within the Swift energy band.

Around 20% of the SGRBs detected by Swift have been followed by an extended emission lasting up to 100 s (hereafter SGRB-EE) (Norris & Bonnell 2006; Perley et al. 2008), leading to suggestions that different progenitor types produce these bursts (Norris, Gehrels & Scargle 2011). Troja et al. (2008) argue that SGRB-EE could be NS-BH mergers based on their galaxy off-sets. Other candidate systems include the birth of a rapidly rotating proto-magnetar produced via NS-NS merger or accretion-induced collapse of a white dwarf (Metzger et al. 2008; Bucciantini et al. 2011). In the following, we have considered separately the normal SGRBs and the SGRB-EE to take this uncertainty in the progenitor nature into account.

SGRB observations could potentially play a more important role in constraining compact object merger rates on two fronts as more data become available. Firstly, as a direct consistency check of the binary merger rates inferred from binary pulsars and population synthesis. Secondly, as a constraint on the progenitor scenario and the engine that drives the emissions. Both are critical issues for solving the consistency check of the binary merger rates inferred from binary pulsars and population synthesis. Secondly, as a direct consistency check of the binary merger rates inferred from binary pulsars and population synthesis. Secondly, as a constraint on the progenitor scenario and the engine that drives the emissions. Both are critical issues for solving the consistency check of the binary merger rates inferred from binary pulsars and population synthesis.

Within 5 years, co-ordinated gamma-ray, X-ray, optical and gravitational-wave observations may allow the strong gravity regime of the central engine of compact object mergers to be probed. Such ‘multi-messenger’ observations provide the opportunity to probe these events across a vast energy spectrum, and to constrain the progenitor populations of SGRBs. Furthermore, co-ordinated optical and gravitational-wave searches may play an important role in confirming the first direct gravitational-wave observations of compact object mergers (Coward et al. 2011). It is becoming increasingly important to constrain the rate of compact object mergers and their proposed optical counterparts in the context of up-coming gravitational-wave searches.

The scarcity of SGRB observations and the poorly understood biases in the current data have made it challenging to calculate the SGRB rate density with meaningful uncertainties. Previous work using GRB flux-limited samples either assumes, or derives models for, the SGRB luminosity function and rate evolution of the sources; e.g. Guetta & Piran (2006) find a SGRB rate density of $8 \, - \, 30 \, Gpc^{-3} \, yr^{-1}$, assuming isotropic emission. Another study (Diwetz et al. 2011), calculates a higher NS-NS merger rate of about 7800 Gpc$^{-3} \, yr^{-1}$, but assuming the emissions are beamed with small opening angles.

In this study, we calculate a beaming-corrected SGRB rate density using the Swift sample of SGRB peak fluxes, redshifts and inferred beaming angles from X-ray observations. For our GRB selection criteria we use the Jochen Greiner catalogue of localized GRBs (see Table 1) and select bursts indicated as short that have reliable redshifts up to 2012 April. From this selection of 9 bursts, we omit the burst GRB 090426, which is possibly linked to the death of a massive star based on its galaxy off-set and optical and x-ray emissions. We note also that although GRB 100816A has shown certain characteristics not consistent with a SGRB classification it cannot be clearly ruled out; additionally, its redshift of $z = 0.8$ will not influence our results significantly.

We avoid using a SGRB luminosity function, models for progenitor rate evolution, and a beaming angle distribution, all of which have large uncertainties. Instead, we focus on observed and measured parameters that take into account detection selection effects that modify Swift’s detection sensitivity to SGRBs. Finally, we use our SGRB rate density estimates to infer a detection rate of binary NS mergers by Advanced LIGO (aLIGO) and Virgo interferometers. Despite the poor statistics, this approach gives meaningful results and can be followed up when a larger sample of SGRB observations becomes available.

2 SGRB BEAMING CONSTRAINTS

The currently favoured emission model for SGRBs is a compact object merger triggering an explosion causing a burst of collimated $\gamma$-rays (Eichler et al. 1984; Narayan, Paczynski & Piran 1992; Lee Ramirez-Ruiz & Granot 2003) powered by accretion onto the newly formed compact object. The ultra-relativistic outflow is eventually decelerated by interaction with the interstellar medium to produce a fading X-ray and optical afterglow. After the jet Lorentz factor $\Gamma$ decreases to $\Gamma \sim \theta^{-1}$, where $\theta$ is the jet opening half angle, the afterglow becomes observable from viewing angles greater than $\theta_i$. 

© 3002 RAS, MNRAS 000, L12
Only two SGRBs have identifiable jet breaks (see Coward et al. 2011, and references therein): GRB 050709 ($\theta_j \sim 14^\circ$ – detected by the HETE satellite) and GRB 051221 ($\theta_j \sim 7^\circ$). These beaming angles are not necessarily agreed upon, mainly because the afterglow jet break times obtained from X-ray or optical light curves are notoriously difficult to identify at late times, and the emissions are generally fainter in X-rays and optical compared to those of long bursts. Furthermore, the inferred beaming angles are model dependent (Sari, Piran & Halpern 1999) and sensitive to the circumburst environment.

For the following rate density calculations, we employ the standard fireball model (e.g. Sari et al. 1999) to estimate the jet opening half angle using the minimum jet break times from X-ray observations:

$$\theta_j = 0.161 [t_j/(1+z)]^{3/8} (n \eta/E_{iso})^{1/8} \text{rad},$$

where $t_j$ is the jet break time, is the time in days when the light curve decay index changes from $\sim 1$ to $\sim 2$. The parameter $n$ is the circum-burst density, in cm$^{-3}$, $\eta$ is the fraction of GRB energy observed in the prompt emission, and $E_{iso}$ is the prompt isotropic equivalent energy in 10$^{51}$ erg. We assume an average of $n = 1$ cm$^{-3}$ and $\eta = 0.1$ for our SGRB sample.

The circum-burst density for both long and short duration GRBs is quite scattered, and typically ranges from (0.001-10)cm$^{-3}$. Kopac et al. (2012) showed that $n$ for SGRBs is similar to the one derived for long bursts (Gendre, Corsi & Piro 2006), implying that the local density should be similar for both collapsars and mergers. Contrary to this, Fong et. al. (2012) argue that SGRBs are located in typically smaller circum-burst densities, supported by their constraint of $n = 0.01 - 0.1$ cm$^{-3}$ for GRB 111020A. For definiteness, we use 0.01 cm$^{-3}$, to calculate lower limits on the beaming angle for SGRBs without a measured jet-break. Alternatively, for the SGRB-EE sample we use $n = 1$ cm$^{-3}$, because the only confirmed SGRB-EE with a jet break, GRB 060614, is constrained to $n = 10$ cm$^{-3}$ (Della Valle 2006).

The difficulty of measuring jet breaks leads to a bias in obtaining jet angles favouring those bursts that have very bright X-ray/optical afterglows and/or relatively short jet break times. Hence, the true average of the SGRB jet angle distribution will be greater than that based on the very small sample used in this work. Nonetheless, given the lack of knowledge of the SGRB angle distribution, both theoretically and observationally, we choose to employ the small number of inferred SGRB beaming angles and lower limits from X-ray/optical observations.

To extend the very small measured beaming angle sample, we constrain the minimum beaming angles for those SGRBs that have X-ray afterglow light curves available up to at least 1 day from the trigger. The following five SGRBs: GRB 100816A, GRB 071227A, GRB 070714B, GRB 061006 and GRB 050724 satisfy this criterion. We set a lower limit on the jet opening angle from the time when the Swift XRT monitoring stopped. We compute $E_{iso}$, from the literature, if available, or from the quoted fluences in the GCN circulars by estimating the corresponding $E_{iso}$ in the 1–10$^{51}$ keV rest-frame energy range. For the GRB energy spectrum, we use the broken power law fit, termed the Band model (Band 2000), or cut-off power law with spectral parameters where known. If the spectral parameters are unknown we simply rescale the fluence by $4\pi d_L^2/(1+z)$, where $d_L$ is the luminosity distance.

### Table 1. SGRB peak fluxes, $T_90$ and redshifts taken from the Swift online catalogue and \url{http://www.mpe.mpg.de/~jcg/grbgen.html} used to calculate Poisson rates. We use the 20-ms peak photon fluxes from the BAT2 catalogue where possible – those marked by * are 1-s peak photon fluxes. We set a lower limit on the jet opening angle from the time when the Swift XRT monitoring stopped.

### 3 EMPIRICAL SGRB RATE MODEL

A Poisson GRB rate can be estimated from small number statistics using $V_{max}^2$ (Piran 1992; Cohen & Piran 1993), where $V_{max}$ is the maximum volume within which a SGRB with observed peak flux, $F_p$, could be detected for a given satellite detector with detection sensitivity $F_{limit}$. While $V_{max}$ has been used previously (e.g. Guetta & Della Valle 2007) to estimate rates of low-luminosity GRBs (see also Coward 2005), we extend the rate estimate method to account for biases in the Swift GRB redshift and peak flux sample.

Firstly, the low energy detection bandwidth of Swift (15–150 keV) in comparison with BATSE’s 50–300 keV results in a bias against SGRBs which typically have harder emissions. Secondly, the Swift detection threshold is not sim-
x

ply defined by the detector sensitivity, but by a complex triggering algorithm. Both these effects manifest as a bias against Swift detecting SGRBs; i.e. a smaller proportion of bursts has been detected by Swift (~10%). The latter effect results from the detection process employed by BAT, the Swift coded-aperture mask γ-ray detector. In addition to requiring an increased photon count rate above background (the sole triggering criterion used for BATSE), BAT employs a second stage in which an image is formed by accumulating counts for up to 26 s [Band (2003)].

We attempt to crudely correct for these biases by using the observed SGRB rate from BATSE as a rate calibration for the Swift SGRB rate. Because BATSE operated at different energy thresholds and trigger sensitivities, for consistency we take all BATSE SGRBs with 64-ms peak flux when the trigger threshold was set to 5.5 σ in the 50–300 keV energy range (total live operation time of 3.5 years). This yields 32 SGRBs sr$^{-1}$ yr$^{-1}$, assuming an effective BATSE FoV of π sr [Band (2003)]. The ratio of the rate of BATSE to Swift SGRBs, $R_{B/S} = 6.7$, is used to calibrate the observed Swift SGRB rate to estimate an intrinsic SGRB rate.

Because SGRBs occur over a short duration, it is more difficult (compared to long bursts) to produce a significant signal above background. Hence instead of using the theoretical BAT sensitivity of $F_{\text{lim}} = 0.4$ ph s$^{-1}$ cm$^{-2}$, we employ a flux limit of 1.5 ph s$^{-1}$ cm$^{-2}$, using the smallest 20-ms peak flux from the SGRB data.

Another detector-dependent selection effect arises from the limited energy bandpass of Swift, i.e. (15–150) keV. What is measured by Swift is not the bolometric peak flux, but a detector response and source-spectrum dependent peak flux. We define the bolometric isotropic-equivalent luminosity correction factor [Imerito et al. (2009)]:

$$C_{\text{det}}(e_1, e_2) \equiv \frac{\int e_1 E N(E) dE}{\int e_1 E N(E) dE},$$

where $[E_1 = 1, E_2 = 10000]$ keV spans the bolometric gamma-ray spectrum, and $[e_1, e_2]$ is the sensitivity band of Swift, i.e. 15 to 150 keV. For the source energy spectrum, $N(E)$, we employ the Band function [Band (2006)], with spectral indices $\alpha = -1$, $\beta = -2.3$ and a rest-frame power-law break energy of 511 keV.

In addition, for high redshift sources, a higher energy component of the source spectrum is redshifted into the sensitivity band of the detector. The following factor, $k(z)$, accounts for the downshift of γ-ray energy from the burst to the observer’s reference frame:

$$k(z) \equiv \frac{\int e_2 E N(E) dE}{\int (1+z)e_1 E N(E) dE}. \quad (3)$$

Taking into account the sensitivity reduction and k-correction, the SGRB all-sky rate can be inferred from the flux-limited SGRB sample in Table 1. We calculate the maximum distance $d_{\text{max}}$, with corresponding redshift $z_{\text{max}}$, that a burst at luminosity distance $d_L$ could be detected given Swift’s sensitivity $F_{\text{lim}}$:

$$d_{\text{max}} = \sqrt{\frac{F_{\text{p}} k(z)}{F_{\text{lim}} k(z_{\text{lim}})}} d_L(z), \quad (4)$$

where $F_{\text{p}}$ is the observed peak flux and $k(z_{\text{lim}})$ is the k-correction for a burst at the maximum limiting distance of detection for the sample. Given the large uncertainty in the SGRB luminosity function, we use the largest redshift from our sample, $z_{\text{lim}} = 0.92$. We note that the bolometric correction, $C_{\text{bol}}(e_1, e_2)$, cancels out in the above equation, because it is independent of redshift.

The corresponding maximum SGRB detection volume for each burst is defined as

$$V_{\text{max}} = \int_0^{z_{\text{max}}} \frac{dV}{dz} dz, \quad (5)$$

where the volume element factor, $dV/dz$, and luminosity distance, $d_L(z)$, are calculated using a flat-Λ cosmology with $H_0 = 71$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_M = 0.3$ and $\Omega_{\Lambda} = 0.7$. This estimate (Eq. 5) is valid as long as the rate of SGRBs does not change significantly over the range (0, $z_{\text{max}}$). Since the detection range of SGRBs is quite small and typically $z < 1$ this approximation is valid.

To calculate the intrinsic rate of SGRBs requires accounting for the beaming angle, $\theta_0$, of the jetted burst. Equation (6) expresses the beaming factor used to correct for the unobserved SGRBs that are not detected because the jet is misaligned with the detector:

$$B(\theta_0) = [1 - \cos(\theta_0)]^{-1}. \quad (6)$$

To account for the fact that only a fraction of observed SGRB have measured redshifts, we scale the rate density by the ratio of Swift bursts with redshift to those without redshifts, $F_r$. We use $F_r \approx 8/39$ and 6/12 for SGRB and SGRB-EE respectively. The time span encompassing all observations, $T \sim 6$ yrs, is defined by the start of Swift observations to the time of the most recent SGRB in the sample and we account for the fractional sky coverage of Swift, $\Omega \approx 0.17$. To account for Swift’s reduced sensitivity for detecting SGRBs relative to BATSE, we use the ratio of the BATSE to Swift SGRB detection rate, which we approximate as $R_{B/S} = 6.7$. This converts the Swift SGRB rate to an intrinsic SGRB rate. We point out that this correction applies only to SGRB, and not SGRB-EE, because Swift is more sensitive to these longer emission bursts.

Finally, we calculate the probability of a GRB to be a non-collapsar, $P_{(T_{\text{90}}, P_L)}$ [Bromberg et al. 2012], based on its $T_{\text{90}}$ and a power-law fit to the gamma-ray spectrum in the 15 – 150 keV band. The study was refined (Bromberg et al. 2012b) to show that a GRB with a hard power-law photon index ($P_L < 1.15$) has a larger chance of being a non-collapsar than a GRB with a soft photon index at the same $T_{\text{90}}$. We note that these probabilities do not influence the magnitude of the calculated rate densities significantly in this work.

Combining all detection parameters yields the Poisson SGRB rate density of a single ($i$th) burst, and the total rate density for $n$ bursts:

$$R_{\text{SGRB}} = \sum_{i=0}^{n} \frac{1}{V_{(i_{\text{max}})}} F_r T \Omega R_{B/S} B_i(\theta_0) P_{(T_{\text{90}}, P_L)}. \quad (7)$$

SGRBs may track the star formation rate history (SFR), albeit with a time delay. The $z_{\text{max}}$ that we derive for the most significant contributions to the rate density range from $z = 0.2 – 0.4$. To investigate the effect of including SFR evolution, we recalculated a local rate density using an integrated differential rate equation using several different SFR
models and volumes bounded by \(z_{\text{max}}\). We find differences of a factor of about 2 between the local rate densities calculated using equation (7) and an integrated differential rate model. Also, there are discrepancies at small-\(z\) using different SFR models, highlighting that the models are not good fits at small \(z\). Given that the uncertainties in the small \(z\) SFR are of the same scale as the change in the SFR from \(z = 0 - 0.3\), e.g. see figure 10 in Reddy & Steidel (2009), we do not include an evolution of the SGRB rate density in space.

We calculate lower rate estimates assuming no beaming. Upper rates are estimated using the observed beaming angle constraints for each burst, and if a beaming angle estimate is unavailable, we use the smallest inferred jet angle from the data, \(\theta_j \sim 7^\circ\). Given that the inferred average beaming angle of the jet is biased towards SGRBs with short jet-break times (see §3), our upper rate limit estimate is at the limit of plausibility.

We use the above SGRB rate density to infer a detection rate of binary NS mergers by advanced gravitational-wave interferometers. For aLIGO and Virgo interferometer sensitivities, the horizon distance, \(D_h\) (all sky locations and orientation averaged over) for optimal detection of a NS-NS merger in a coincidence search is about 340 Mpc (cosmological redshift not included). For a direct comparison with Ab10, the detection rate is computed considering the noise power spectral density of a single interferometer, with \(D_h = 197\) Mpc. Given the uncertainty in the beaming angle distribution, we define an optimal detection rate as a function of \(\theta_j\) using the SGRB lower rate estimate, i.e. from \(\theta_j = 90^\circ\), scaled by \(B(\theta_j)\) and the Euclidean volume:

\[
R(\theta_j) = \frac{4\pi}{3} D_h^3 R_{\text{Low}} B(\theta_j). \tag{8}
\]

### 4 RESULTS

We have focussed on the sensitivity of Swift for detecting SGRBs, and highlight several important issues. The complex triggering algorithm of the BAT is biasing detection against SGRBs, and this should be considered when attempting to estimate an intrinsic rate density of SGRBs. The rate estimates using \(V_{\text{max}}\) are sensitive to the flux limit of the detector, but are mostly invariant to the bolometric and k-correction because these effects cancel out. We also note that SFR evolution may increase the calculated SGRB rate density by \(\sim 2\) in the small-\(z\) regime.

With the above caveats, Table 2 shows the rate densities of SGRB and SGRB-EE using equation (7) applied to each burst, with the observed constraints on \(\theta_j\). The total lower and upper rate densities for SGRBs are \(8^{+3}_{-1}\) (assuming isotropic emission) and \(1100^{+700}_{-340}\) Gpc\(^{-3}\) yr\(^{-1}\) (assuming beaming—see Table 2) respectively, where the errors are the 95% Poisson statistics (Gehrels 1986). The SGRB rate density is dominated by GRB 080905A, which was relatively faint and nearby, with a \(z_{\text{max}} \approx 0.3\). Because of the uncertainty in the redshift of this burst, we also calculate a rate density excluding GRB 080905A, and find total and upper rate densities of \(3^{+2}_{-1} - 500^{+140}_{-220}\) Gpc\(^{-3}\) yr\(^{-1}\). To test the robustness of the total rate density given that only a few SGRBs contribute significantly to the sum, we used “jackknife” on the summed SGRB rates in Table 2. The standard error was found to be \(\pm 240\) Gpc\(^{-3}\)yr\(^{-1}\), which is less than the Poisson counting error and the beaming angle uncertainty.

| SGRB | \(P_{(T_0) P_L}\) | lower rate Gpc\(^{-3}\) yr\(^{-1}\) | upper rate Gpc\(^{-3}\) yr\(^{-1}\) |
|------|----------------|-------------------------------|-----------------------------|
| 091117A | 0.79 | 0.039 | 5.3* |
| 090510 | 0.89 | 0.02 | 2.7* |
| 080905A | 0.72 | 4.9 | 660* |
| 070724A | 0.84 | 0.77 | 140 |
| 061217 | 0.89 | 0.2 | 27* |
| 051221A | 0.72 | 0.026 | 3.5 |
| 050509B | 0.79 | 2 | 270* |
| Total rate | \(8^{+5}_{-3}\) | \(1100^{+700}_{-340}\) |

**Table 2.** The beaming-corrected SGRB rate densities with Poisson uncertainties using the observed constraints on \(\theta_j\) and scaled by the probability \(P_{(T_0) P_L}\). (GRB 100816A, which uses just the \(T_0\). Lower rate estimates assume isotropic emission, and upper rates use the observed beaming angle constraints shown in Table 1, or the smallest observed beaming angle in the sample*. \(\theta_j \approx 7^\circ\). We calculate the SGRB-EE rate density separately, noting that \(T_0\) is generally much larger than 2 s, as shown in Table 1.

* Because of the importance of GRB 080905 for the rate density, and its uncertainty (see Table 1. for caveats), we also calculate total rates excluding this burst i.e. \((3^{+2}_{-1} - 500^{+140}_{-220})\) Gpc\(^{-3}\) yr\(^{-1}\).
5 DISCUSSION

It has been suggested that the observed SGRB population is presently not a useful constraint on rate estimates for compact binary mergers (Ab10). The justification of this argument stems from the fraction (if any) of binary NS mergers that will produce an SGRB. Another issue is that SGRB observation stems from the fraction (if any) of binary NS mergers presently not a useful constraint on rate estimates for compact binaries. It has been suggested that the observed SGRB population is biased to the brighter bursts that are nearby (Coward et al. 2008; Coward 2009; Imerito et al. 2009). Hence, for the majority of bursts with a faint afterglow, redshift measurement is more difficult. We attempt to crudely correct for this bias by boosting the calculated rate by the fraction of bursts without measured redshift to those with redshift, assuming the missing redshifts follow the same distribution as the observed redshifts. This assumption is reasonable (in this work) because the rate density is dominated by those faint bursts in the smallest $V_{\text{max}}$.

Hence, there are two main sources of selection effects and biases. Firstly, there are the satellite detectors, exemplified by the significant difference between BATSE and Swift SGRB detection efficiencies. Secondly, there is the problem of obtaining a redshift either from the host galaxy or the afterglow itself (as highlighted above). We have shown that these detection biases should be considered when attempting to use the current (and future) SGRB detections for constraining rate evolution, rate densities and linking SGRBs to binary NS mergers.

The binary NS gravitational-wave detection rate estimates are based on calculating an intrinsic SGRB rate density using Swift localized bursts, taking into account dominant selection effects. This approach, based on observational data, is very different from that based on Galactic binary pulsar observations and modelled population synthesis. In the latter, Ab10 use the observed Galactic binary pulsar population and extrapolate a NS merger rate density out to the aLIGO and Virgo detection horizon. Conversely, our approach avoids this extrapolation because it is essentially an observed rate extending well beyond the average sensitivity distances of the upcoming gravitational-wave searches for compact binaries (about 300 Mpc or $z = 0.07$ for aLIGO and Virgo interferometers) and, moreover, a significant fraction of SGRBs are observed in association with evolved stellar populations.

In conclusion, the upcoming gravitational-wave detection era will be fundamental for resolving the SGRB–binary NS merger connection, since an unequivocal association between SGRBs and binary NS mergers will only be possible via coincident gravitational-wave and electromagnetic observations. Ultimately, a comparison between the SGRB rate density and the gravitational-wave detection rate will help constrain the fraction of binary NS mergers that give rise to SGRBs and the SGRB beaming angle distribution.
