ABSTRACT

Background & Objective: Freezing of gait (FOG) is accompanied by various complications, reduced quality of life, and increased risk of mortality and morbidity in patients with Parkinson’s disease. The incidence of this disabling phenomenon can be predicted in at least one-third of patients with Parkinson’s disease. Therefore, the current study aimed to investigate the prevalence of FOG among Iranian patients with Parkinson’s disease and to determine the predictors of this phenomenon in these patients.

Materials & Methods: This cross-sectional study was performed on 135 patients with Parkinson’s disease, referred to Rasoul Akram Hospital, Tehran, Iran. The subjects were selected using the convenience sampling method. FOG was confirmed via clinical examination by two fellows of the movement disorder fellowship program. Variables were evaluated using bivariate and multivariate logistic regression analyses, receiver operating characteristics (ROC) curve analysis, and measurement of the area under the ROC curve (AUC).

Results: Out of 135 patients with Parkinson’s disease, 36 (26.7%) had FOG. Based on the results, FOG had a significantly higher prevalence in older patients, compared to younger patients. According to the results, FOG had no significant relationship with other baseline variables, including gender, disease duration, and disease manifestations. According to the multivariate logistic regression model, advanced age (OR: 0.915; P=0.031) and longer disease duration (OR: 0.992; P=0.019) predicted the incidence of FOG in the presence of underlying factors.

Conclusion: The prevalence of FOG among patients with Parkinson’s disease was estimated at 26.7%, which is within the global range. The results revealed that age and duration of disease were two factors, which could predict the occurrence of FOG with high sensitivity and specificity.

Keywords: Determinants, Freezing of Gait, Parkinson’s disease, Prevalence, Risk Factors

Introduction

Freezing of gait (FOG) is a form of episodic gait disturbance among patients with Parkinson’s disease in the absence of a specific cause (1). This condition is also described as a severe and sudden disturbance in walking (2). However, no precise neurological pathogenesis has yet been identified for FOG (3). Evidence suggests that this disorder is not only limited to Parkinson’s disease, but responses to dopaminergic and non-dopaminergic drugs may also be the cause (4).

Different hypotheses have been proposed regarding the pathogenesis of FOG. The occurrence of FOG seems to be associated with a disruption in the process of gait coordination at the level of the spinal cord (5). Some researchers have also emphasized on tremor in the legs in a standing position, being related to the impaired coordination of flexor and extensor muscles contraction (6). Another hypothesis suggests the lack of movement automation in the central coordination of muscles being involved in walking (7).

Some imaging studies, such as magnetic resonance imaging (MRI), have also shown a significant reduction in the level of blood oxygenation, especially...
in the vascular pathways of the frontal area (8,9). In
general, the lack of coordination in the motor function
of the cortex, as well as the spinal cord coordination
center, plays a significant role in FOG, especially in
Parkinson’s disease patients. FOG mainly results in
inability to move, disturbance of daily activities, and
impaired quality of life (10). The identification of risk
factors associated with the occurrence of FOG, which
may completely vary across different societies, can
contribute to the early diagnosis, prediction, and
treatment of this disorder. Therefore, it is essential to
first estimate the prevalence and risk factors of FOG in
every population.

In the present study, we aimed to determine the
prevalence of FOG among Iranian patients with
Parkinson's disease and to assess the factors predicting
this disabling phenomenon.

Materials and Methods

This cross-sectional study was performed on patients
with Parkinson’s disease, referred to Rasoul Akram
Hospital, Tehran, Iran, in 2015. The FOG was detected,
based on the initial interview with the patient and
physical examination in the clinic. Videos were
recorded from the patients and checked by two fellows
of the movement disorder fellowship program,
according to their objective judgment. Also,
Parkinson’s disease was diagnosed, according to the
Movement Disorder Society criteria.

The Student Research Committee of Iran University
of Medical Sciences (ethical code: IR.IUMS.rec.
1393.93-02-193-24848) approved the current study.
All subjects signed an informed consent form before
participating in the study.

Statistical Analysis

The quantitative variables were expressed as mean
and standard deviation, and the categorical variables
were described as absolute frequencies and percentages
(11,12). Normality of the data was determined by
means of the Shapiro–Francia test (13). The
comparison of the categorical variables was performed
using Chi-square test or Fisher's exact test when more
than 20% of the cells with the expected count of < 5
were observed. Furthermore, the quantitative variables
were compared via the t-test or Mann-Whitney U test.
All statistical analyses were performed in SPSS 16.0
(SPSS Inc., Chicago, IL. USA). P-value equal to or less
than 0.05 was regarded as statistically significant
(14,15).

The variables used to assess the anticipation were
gender, disease duration, age, and severity of
Parkinson’s disease (according to the Unified
Parkinson's Disease Rating Scale (UPDRS)).

Results

Out of 135 patients with Parkinson’s disease, 97
(71.9%) were male. The mean age of the subjects was
57.37±12.23 years. Also, the mean duration of the
disease was 50.41±13.44 months. In terms of clinical
manifestations, tremor, rigidity, bradykinesia, and
dyskinesia were observed in 100 (74.1%), 85 (63.0%),
71 (52.6%), and 20 (14.8%) patients, respectively.
Also, 7 (5.2%) patients reported a history of falling.

Out of 135 patients with Parkinson's disease, 36
(26.7%) had FOG. The overall prevalence of FOG was
significantly higher in older patients, compared to the
younger ones (Table 1). Nonetheless, FOG was not
associated with other baseline variables, including
gender and disease severity. Based on the multivariate
logistic regression model (Table 2), advanced age (OR:
0.915; P=0.031) and longer disease duration (OR:
0.992; P=0.019) the occurrence of FOG in the presence
of an underlying cause was predicted.

According to the area under the receiver operating
characteristics curve (AUC) measurements, age was a
significant predictor of FOG occurrence (AUC=0.872).
The best cut-off point for age to predict FOG was 68.5
years, with sensitivity and specificity of 94.4% and
59.6%, respectively (Figure 1). The disease duration
could also predict FOG (AUC=0.863). The best cut-off
point for disease duration was 57.5 months, with a
sensitivity of 100% and specificity of 72.7% for
predicting FOG in patients with Parkinson’s disease
(Figure 2).

| Table 1. Prevalence of freezing of gait based on baseline variables |
|-------------------------|-------------------------|-------------------------|
| **Gender**              | **Prevalence of freezing of gait** | **P-value** |
| Male                    | 28 (28.9)               | 0.365                  |
| Female                  | 8 (21.1)                |                        |
| **Age group**           |                          | 0.001                  |
| ≤60 years               | 15 (17.4)               |                        |
| Factor      | Prevalence of freezing of gait | P-value |
|------------|-------------------------------|---------|
| >60 years  | 21 (42.9)                     |         |
| Disease duration |                               |         |
| ≤50 months | 25 (18.5)                     | 0.032   |
| >50 months  | 47 (34.8)                     |         |
| Tremor     |                               |         |
| Positive   | 27 (27.0)                     | 0.882   |
| Negative   | 9 (25.7)                      |         |
| Rigidity   |                               |         |
| Positive   | 25 (29.4)                     | 0.347   |
| Negative   | 11 (22.0)                     |         |
| Bradykinesia |                               |         |
| Positive   | 23 (32.4)                     | 0.113   |
| Negative   | 13 (20.3)                     |         |

Table 2. Multivariate logistic regression model of factors predicting freezing of gait in patients with Parkinson’s disease

| Index      | Odds ratio | Lower limit | Upper limit | P-value |
|------------|------------|-------------|-------------|---------|
| Gender     | 1.803      | 0.664       | 4.897       | 0.247   |
| Age        | 0.915      | 0.845       | 0.992       | 0.031   |
| Duration   | 1.092      | 1.014       | 1.176       | 0.019   |
| Constant   | 2.284      | ---         | ---         | 0.524   |

Discussion

The incidence of FOG is predictable in at least 30% of patients with Parkinson’s disease. This condition is accompanied by various complications, such as walking disorders and disturbances in orientation and balance. Accordingly, this disabling phenomenon can increase the risk of falling and even lead to the development of cognitive, visual, and auditory abnormalities, thereby impairing the quality of life and increasing the risk of mortality and morbidity.

The current study aimed to investigate the prevalence of FOG in Iranian patients with Parkinson’s disease and to investigate the predictors of this phenomenon in these patients. The identification of these factors not only can facilitate the early diagnosis of FOG, but also can improve the patient’s survival. In the present study, the prevalence of FOG was estimated at 26.7%, which is similar to the rate reported in various studies. In a systematic review, the prevalence of FOG was reported to range from 20% to 63% (16). In a study by et al., the incidence of FOG ranged from 16.1% to 51.6%, depending on the duration of disease (17). Also, in a study by Amboni et al., an incidence rate of 54.3% was reported for FOG (18). Moreover, in studies conducted by Forsaa et al. and Contreras et al., the prevalence of FOG was estimated at 38.2% and 44.4%, respectively (19, 20). The discrepancy between the results can be attributed to differences in the sample size or disease severity in these studies.

In the current study, older age and longer disease duration were identified as strong predictors of FOG. The results showed that almost all patients above the age of 68 years, as well as patients with a disease duration of more than five years, were severely affected by FOG. Overall, different predictors have been introduced for FOG in various studies; however, age and duration of disease were found to be the most important ones. In a previous study, the incidence of FOG was 16.1%, 39.5%, and 51.6% after one, two, and three years of the disease, respectively (17). Moreover, a previous study examined the association of FOG incidence with a disease duration of more than three years, suburban living, low literacy, akinetic-rigid syndromes, indiscriminate use of levodopa, a high daily dose of levodopa, and failure to use amantadine or dopamine receptor agonists (15). However, in the current study, it was not possible to evaluate the effects of pharmaceutical information and socioeconomic factors on the incidence of FOG due to the lack of adequate patient information.

In consistence with our results, a previous study reported that patients with FOG had a longer duration of disease, a more severe disease, and more disabilities (16). Also, another study reported motor fluctuation and a high dose of levodopa as predictors of FOG; however, these variables were not investigated in our study (17). Overall, in previous studies, patients with FOG and a longer duration of Parkinson’s disease had a higher Unified Parkinson’s Disease Rating Scale (UPDRS)
score, higher daily levodopa dose, and more exposure to antimuscarinic drugs (21). The longer duration of Parkinson’s disease and higher UPDRS scores were reported as the predictors of FOG. Both factors showed high specificity in the prediction of FOG, despite their low specificity. Therefore, the majority of studies have confirmed the central role of age and duration of disease as two predictors of FOG (19).

Since this is the first study conducted in Iran on FOG, more attention must be paid to this phenomenon, and more appropriate treatments must be prescribed. However, a limitation of this study was that it did not examine the effects of variations in the blood concentration of levodopa or in the level of cognition on the physical status of patients.

Conclusion

The prevalence of FOG among the Parkinson’s disease patients was estimated as 26.7%, in Iran, which is within the global range. The results revealed age and duration of illness as two factors predicting the occurrence of FOG with high sensitivity and specificity. Further studies should be performed to investigate the role of other factors, such as drug and therapeutic approaches, in the prediction of FOG occurrence in our society.
