Abstract

We consider a variant of the well-studied gossip-based model of communication for disseminating information in a network. Classically, in each time unit, every node \( u \) is allowed to contact a single random neighbor \( v \). If \( u \) knows the data (rumor) to be disseminated, node \( v \) learns it (known as push) and if node \( v \) knows the rumor, \( u \) learns it (known as pull). While in the classic gossip model, each node is only allowed to contact a single neighbor in each time unit, each node can possibly be contacted by many neighboring nodes. If, for example, several nodes pull from the same common neighbor \( v \), \( v \) manages to inform all these nodes in a single time unit.

In the present paper, we consider a restricted model where at each node only one incoming request can be served. As long as only a single piece of information needs to be disseminated, this does not make a difference for push requests. It however has a significant effect on pull requests. If several nodes try to pull the information from the same common neighbor, only one of the requests can be served. In the paper, we therefore concentrate on this weaker pull version, which we call restricted pull.

We distinguish two versions of the restricted pull protocol depending on whether the request to be served among a set of pull requests at a given node is chosen adversarially or uniformly at random. As a first result, we prove an exponential separation between the two variants. We show that there are instances where if an adversary picks the request to be served, the restricted pull protocol requires a polynomial number of rounds whereas if the winning request is chosen uniformly at random, the restricted pull protocol only requires a polylogarithmic number of rounds to inform the whole network. Further, as the main technical contribution, we show that if the request to be served is chosen randomly, the slowdown of using restricted pull versus using the classic pull protocol can w.h.p. be upper bounded by \( O(\Delta/\delta \cdot \log n) \), where \( \Delta \) and \( \delta \) are the largest and smallest degree of the network.
1 Introduction

Gossip-based communication models have received a lot of attention as a simple, fault-tolerant, and in particular also scalable way to communicate and disseminate information in large networks. The classic application of gossip-based network protocols is the spreading of information in the network, specifically the problem of broadcasting a single piece of information to all nodes of a network, in this context also often known as rumor spreading, e.g., [5, 6, 8, 10, 11, 14]. On top of this, gossip-based protocols have for example also been proposed for applications such as maintaining consistency in a distributed database [6], for data aggregation problems [4, 15, 16], or even to run arbitrary distributed computations [2].

The best studied gossip strategy is the random phone call model, which was first considered in [10]. Typically, time is divided into synchronized rounds and in a given network $G$, in each round, every node can contact a random neighbor and if $u$ contacts $v$, an interaction between $u$ and $v$ is initiated for the current round. For spreading a rumor, two basic modes of operation are distinguished. Nodes that already know the rumor can PUSH the information to the randomly chosen neighbor [10] or nodes that do not yet know the rumor can PULL the information from the randomly chosen neighbor [6]. In much of the classic work, the network $G$ is assumed to be a complete graph. In that case, it is not hard to see that PUSH and PULL both succeed in $O(\log n)$ rounds and that the total number of interactions of each node can also be bounded by $O(\log n)$. In [14], it is shown that when combining PUSH and PULL (in the following referred to as PUSH-PULL), the average number of interactions per node is only $\Theta(\log \log n)$.

Mostly in recent years, PUSH, PULL, and PUSH-PULL have also been studied for more general network topologies, e.g., [3, 5, 8, 9, 11–13], with [5, 11] and [12, 13] studying the time complexity as a function of the graph’s conductance and vertex expansion, respectively. E.g., in [11], it is shown that with high probability (w.h.p.), the running time of PUSH-PULL can always be upper bounded by $O((\log n)/\phi(G))$, where $n$ is the number of nodes and $\phi(G)$ is the conductance of the network graph $G$.

While in gossip protocols, each node can initiate at most one interaction with some neighbor, even if each node contacts a uniformly random neighbor, the number of interactions a node needs to participate in each round can be quite large. In complete graphs and more generally in regular graphs, the total number of interactions per node and round can easily be upper bounded by $O(\log n)$. However in general topologies a single node might be contacted by up to $\Theta(n)$ neighboring nodes. As an extreme case, consider a star network where a single center node is connected to $n - 1$ leaf nodes. Even if the rumor initially starts at a leaf node, PUSH-PULL manages to disseminate the rumor to all nodes in only 2 rounds. Clearly, in these 2 rounds, the center node has to interact with all $n - 1$ leaf nodes. In some cases, this behavior might limit the implementability and thus the applicability of the proven results for this gossip protocol. In order to obtain scalable systems, ideally, we would like to not only limit the number of interactions each node initiates, but also the number of interactions each node participates in.

In the present paper, we therefore study a weaker variant of the described random gossip algorithms. In each round, every node can still initiate a connection to one uniformly random neighbor. However, if a single node receives several connection requests, only one of these connections is actually established. When disseminating a rumor by using the PUSH protocol, this restriction does not limit the progress of the algorithm. In a given round, a node $v$ learns the rumor if and only if at least one PUSH request arrives at $v$. However, when using the PULL protocol, the restriction can have a drastic effect. If a node $v$ receives several PULL requests from several nodes that still need to learn the rumor, only one of these nodes can actually learn the rumor in the current round. In our paper, we therefore concentrate on the PULL protocol and we define RPULL (restricted PULL) as the described weak variant of the PULL algorithm: In each RPULL round, every node that still needs to learn the rumor contacts a random neighbor. At every node that knows the rumor, one of the incoming requests (if there are any) is selected and the rumor is sent to the corresponding neighbor. By PUSH-RPULL we denote the combination of RPULL with a simultaneous execution of the classic PUSH protocol.
Contributions. We first consider two versions of the RPULL protocol which differ in the way how one of the incoming requests is selected. Assume that in a given round some informed node \( v \) receives RPULL requests from a set of neighbors \( R_v \). In the adversarial RPULL protocol, an (adaptive) adversary picks some node \( u \in R_v \) which will then learn the rumor. In the random RPULL protocol, we assume that a uniformly random node \( u \in R_v \) learns the rumor (chosen independently for different nodes and rounds). While the choice of which neighbor a node contacts with a request is under the control of the protocol, it is not necessarily clear how one of the incoming requests in \( R_v \) is chosen. If the node can only answer one request per time unit and the requests do not arrive at exactly the same time, the first request might be served and all others dropped. Or even if requests arrive at the same time, it might be the underlying network infrastructure or operating system which picks one request and drops the others. If it is reasonable to assume that the incoming requests are served probabilistically and independently, we believe that random RPULL provides a good model. Otherwise, the adversarial assumption might be more reasonable.

As a first result, we show that there are instances for which there is an exponential gap between the running times of the two RPULL variants. We give an instance where for every source node the random RPULL protocol informs all nodes of the network in polylogarithmic time, w.h.p., whereas, for every source, the adversarial RPULL algorithm requires time \( \tilde{O}(\sqrt{n}) \) to even succeed with a constant probability.

In the second part of the paper, we have a closer look at the performance of the random RPULL protocol. Consider a graph \( G \) and let \( \delta \) and \( \Delta \) denote the smallest and largest degree of \( G \). In each round, in expectation, each informed node receives at most \( \Delta / \delta \) requests. Hence, if an uninformed node \( u \) sends an RPULL request to an informed node, \( u \) should receive the rumor with probability at least \( \Omega(\delta / \Delta) \). Consequently, intuitively, the slowdown of using random RPULL instead of the usual PULL protocol should not be more than \( \tilde{O}(\Delta / \delta) \).\footnote{Here \( \tilde{O} \) hides \( \log(n) \) factors.} We prove that this intuition is correct. For every given instance, we show that if the PULL algorithm informs all nodes in \( T \) rounds with probability \( p \), for the same instance, the random RPULL algorithm manages to reach all nodes in time \( O(T \cdot \frac{\Delta}{\delta} \cdot \log n) \) with probability \( (1 - o(1))p \).\footnote{Actually, \( \frac{\Delta}{\delta} \) can be replaced by \( \max_{\{u,v\} \in E} \deg(u) / \deg(v) \) in all parts of the paper.} While the statement might seem very intuitive, its formal proof turns out quite involved. Formally, we prove a stronger statement and show that a single round of the PULL protocol is w.h.p. stochastically dominated by \( O\left(\frac{\Delta}{\delta} \cdot \log n\right) \) rounds of random RPULL in the following sense. We give a coupling between the random processes defined by PULL and random RPULL such that for every start configuration, w.h.p., the set of nodes informed after \( O\left(\frac{\Delta}{\delta} \cdot \log n\right) \) rounds of random RPULL is a superset of the set of nodes informed in a single PULL round. The same holds for simulating one round of PUSH-PULL with PUSH-RPULL. A similar coupling between rumor spreading algorithms has been done in [1] where the authors couple \( \log(n) \) rounds of asynchronous-with one round of synchronous PUSH-PULL. We also show that for such a round-by-round analysis, our bound is tight. That is, there are configurations where \( \Omega\left(\frac{\Delta}{\delta} \log n\right) \) random RPULL rounds are needed to dominate a single PULL round.

Notation and Preliminaries. Let \( G = (V, E) \) be the \( n \)-node network graph. For a node \( u \in V \), we use \( N(u) \) to denote the set of neighbors of \( u \) and \( d_u = d(u) := |N(u)| \) to denote its degree. Given a set of nodes \( S \subseteq V \), we define \( N_S(u) := N(u) \cap S \) to be the set of \( u \)’s neighbors in \( S \) and \( d_S(u) := |N_S(u)| \) for the number of neighbors of \( u \) in \( S \). The smallest and largest degrees of \( G \) are denoted by \( \delta \) and \( \Delta \), respectively. For a set \( V' \subseteq V \) we denote with \( G[V'] \) the graph induced by \( V' \). To indicate a disjoint union of two sets, i.e., \( A \cup B \) with \( A \cap B = \emptyset \), we write \( A \uplus B \). For a set of natural numbers \( \{1, \ldots, k\} \) we only write \( [k] \).

When analyzing the progress of an algorithm, we typically use \( S \) to be the set of initially informed nodes and \( U \) to be the initially uninformed nodes. Given some algorithm \( \text{ALG} \), the set \( S_t^{\text{ALG}} \) denotes the set of informed nodes after \( t \) rounds of \( \text{ALG} \) when starting with the set \( S_0^{\text{ALG}} := S \) of informed nodes. Analogously, we define \( U_t^{\text{ALG}} \) to be the set of uninformed nodes after \( t \) rounds.
2 Separation of Adversarial and Random RPULL

We want to show that the adversarial RPULL can be exponentially slower than the randomized RPULL on general graphs. To show this, we first establish results on the run time of both algorithms on trees. These results might also be of independent interest.

In a tree network let \( p_{v,u} = (v = v_0, v_1, v_2, \ldots, v_q = u) \) denote the unique path from \( v \) to \( u \), though we use that notation also for the set of nodes on that path, i.e., \( p_{v,u} = \{v, v_1, v_2, \ldots, v_{q-1}, u\} \). Define \( D_p := \sum_{u \in p} d_u \), i.e., the sum of all degrees on the path \( p \).

The next lemma shows that on a tree any form of RPULL is asymptotically as fast as PULL plus an additive term in the order of the degree of the node that initially has the rumor.

**Lemma 2.1.** Let \( G \) be a tree network with \( S_0 = \{r\} \) and let \( u \) be a node in \( U_0 \). Furthermore, let \( \tau \) be the first round in which \( u \in S_r \) holds, i.e., the number of rounds until \( u \) gets informed.

1. \( \mathbb{E}[\tau] = \Theta(D_{p_{r,u}} - d_r) \) for PULL,
2. \( \mathbb{E}[\tau] = \Omega(D_{p_{r,u}} - d_r) \) for every type of RPULL,
3. \( \mathbb{E}[\tau] = O(D_{p_{r,u}}) \) for adversarial RPULL.

**Proof of Lemma 2.1.** (1) We root the tree at the only informed node, \( r \). Note that nodes are not aware of their own parent/child relationships. Consider some time \( t \) at which a node \( r' \) on the path \( p_{r,u} \) is in \( S_r \setminus S_{r-1} \), i.e., it just got informed. Thus its child \( u' \in p_{r,u} \) on the path is not yet informed, i.e., \( u' \in U_t \). In any round \( t' \geq t \), in which \( u' \) is not informed yet, it requests its parent with probability \( 1/d_{u'} \). Thus each uninformed node \( u' \in p_{r,u} \setminus \{r\} \) on the path needs \( \Theta(d_{u'}) \) rounds in expectation before it can get informed. Linearity of expectation proves the claim for PULL.

(2) follows from the fact that RPULL is at most as fast as PULL.

(3) For adversarial RPULL divide all rounds \( t' \geq t \) in which \( u' \) is not yet informed into two types: First rounds in which at least one sibling of \( u' \), i.e., the nodes in \( N(r') \setminus \{u'\} \), requests from \( r' \) and secondly rounds in which no sibling of \( u' \) requests from \( r' \). The first type of rounds is upper bounded by \( d_r \), because every neighbor of \( r' \) stops requesting after receiving the rumor. In expectation \( u' \) gets the rumor after \( d_{u'} \) rounds of type two; thus in expectation \( u' \) is informed within \( O(d_{u'} + d_{u'}) \) rounds. Applying this recursively to all uninformed nodes on the path \( p_{r,u} \), we get the claimed result via linearity of expectation. \( \square \)

**Lemma 2.2.** Let \( G \) be a tree network with \( S_0 = \{r\} \). Then in both random and adversarial RPULL it takes \( O(\max_{\text{path } p} D_p + \Delta \log n) \) rounds to fully inform all nodes in \( V \), w.h.p.

**Proof of Lemma 2.2.** The analysis we use does hold for adversarial RPULL.

First look at a path \( p = p_{r,l} = (r = v_0, v_1, v_2, \ldots, v_q = l) \) from the root to some leaf \( l \) and define \( \Delta_p = \max_{v \in p} d_v \). Let \( T_i \) be the random variable that indicates the round in which node \( v_i \) gets informed and with \( T_0 := 0 \) we can define \( X_i := T_i - T_{i-1} \) for \( m = 1, \ldots, q \), the time node \( v_{i-1} \) needs to pass the information forward to node \( v_i \). For simplicity in the following we define \( u := v_i \) and \( s := v_{i-1} \).

Once \( s \) gets informed, a round is called free if no node in \( N(s) \setminus \{v_{i-2}, u\} \) requests to \( s \), otherwise it is called congested. In a free round, \( u \) gets the rumor with probability at least \( 1/d_s \), i.e., the number of free rounds is upper bounded by a geometric random variable \( Y_{i,\text{free}} \sim \text{Geom}(1/d_u) \). On the other hand, in a congested round, at least one neighbor of \( s \) does get informed, so there can not be more than \( d_s \) such rounds.

In total we get that \( \mathbb{P}(X_i \geq \tau) \leq \mathbb{P}(Y_{i,\text{free}} + d_s \geq \tau) \) for node \( u = v_i \) and with \( T_q = \sum_{i=1}^{q} X_i \) we conclude that \( \mathbb{P}(T_q \geq \tau) \leq \mathbb{P}(\sum_{i=1}^{q} Y_{i,\text{free}} + \sum_{i=1}^{q} d_{v_{i-1}} \geq \tau) \).

Since we are on a tree, those geometric random variables are all independent, and we can apply the Chernoff Lemma A.1. Let \( \Delta_p \) be the largest degree of all nodes on the path excluding \( r \), i.e., \( p_1 = 1/\Delta_p \) in terms of the notation from Lemma A.1. With \( Y = \sum_{i=1}^{q} Y_{i,\text{free}} \) we have \( \mu = D_p - d_r \geq \Delta_p \) and we set
Lemma 2.3. There is a graph does not hold for general graphs. i.e., w.h.p., $v_n$ is informed within $O(D_p + \Delta_p \log n) = O(\max_p D_p + \Delta \log n)$ rounds. In a tree there are at most $n$ root-leaf paths, therefore a union bound over all individual paths concludes the proof. 

Lemma 2.2 shows that random RPULL and adversarial RPULL are essentially the same on trees. This does not hold for general graphs.

Lemma 2.3. There is a graph $G = (V, E)$ of size $\Theta(n)$ with node $r_\alpha \in V$, $\deg(r_\alpha) \leq 3$, such that:
- For $S_0 = \{r_\alpha\}$, w.c.p., the run-time of adversarial RPULL is in $\Omega(\sqrt{n})$.
- For any non-empty $S_0 \subset V$, w.h.p., the run-time of randomized RPULL is in $O(\log^2 n)$.

Proof of Lemma 2.3. A picture depicting the graph can be found in Appendix C.

We use the notation w.h.p.$(k)$ to say that some event holds with high probability with respect to $k$, i.e., with probability at least $1 - 1/k$.

We first introduce a graph type, with size depending on some parameter $k$, that we call a $k$-leaf-connected tree ($k$-LCT). In simple words, a $k$-LCT is a binary tree with $k$ leaves, but with those $k$ leaves being fully interconnected, i.e., forming a clique. Mathematically more precise, a graph $H = (B \cup L, E_B \cup E_L)$ with $|L| = k$ and $|B| = k - 1$ is a $k$-LCT, iff $H_L = (L, E_L)$ is a complete graph over $k$ nodes and $H_B = (B \cup L, E_B)$ is a complete binary tree with its leaves being the nodes in $L$. While $H$ is not strictly speaking a tree, we call nodes in $L$ its leaves, $L(H) = L$ the leaf set, $B(H) = B$ its branch set and the root of $H_B$ we call the root of $H$. Also, every node in $H$ except for its root has a clearly designated parent (defined by $H_B$) and each node in $B$ has two clearly designated children (with respect to the root in $H_B$).

Claim 2.4. Let $G = (V, E)$ be a graph and $H = (V_H, E_H)$ be a subgraph of $G$ that is a $k$-LCT. Furthermore, let any node $v \in V_H$ have at most one connection outside of $V_H$, i.e., $\deg_G(v) \leq \deg_H(v) + 1$. Then, w.h.p.$(k)$, for any non-empty set of nodes in $H$ knowing the rumor, randomized RPULL informs all nodes in $H$ within $O(\log k)$ rounds.

Without loss of generality let there be one node $s$ having the rumor. If $s \in B := B(H)$, i.e., $\deg_G(s) \leq \deg_H(s) + 1 \leq 4$, then we can apply Lemma 2.2 to get that all nodes in $B$ are informed within $O(\log k)$ rounds. Let this be the case. All nodes in $L := L(H)$ have degree at most $k + 1$: $k - 1$ neighbors in $L$, one “parent-node” in $B$ and at most one neighbor in $V \setminus V_H$. Each of them requests to its neighboring parent from $B$ with probability at least $1/(k + 1)$, i.e., in each round, with probability at most $(1 - \frac{1}{k+1})^k < 1/2$, no node in $L$ learns the rumor. By Chernoff, w.h.p.$(k)$, after $O(\log k)$ rounds, at least one node in $L$ knows the rumor. If $x > 0$ nodes in $L$ are informed, then each uninformed node $u$ in $L$ requests from one of those $x$ nodes (or a node in $B$) with probability at least $x/(k+1)$ and with probability at least $(1 - 1/k)^{k-1} > 1/3$ node $u$ is the only node requesting from its target. As long as $x < k/2$, with linearity of expectation, each round the expected number of newly informed nodes in $L$ is in $\Omega(x)$. Once $x \geq k/2$ we can use a similar argument to show that, w.c.p., the number of uninformed nodes goes down by a constant factor each round. Hence, after $O(\log k)$ rounds in expectation, but also w.h.p.$(k)$, all nodes in $L$ are informed.

If initially $s \in L$, then with probability $p \in \{1/4, 1/3\}$ its parent node in $B$ requests from $s$, while at the same time with probability at least $(1 - 1/k)^{k-1} > 1/3$ no other node in $L$ requests from $s$. Hence, after $O(\log k)$ rounds, w.h.p., the parent node gets the rumor from $s$. The rest follows from reduction to the first case.
We construct \( G = (V_1 \cup V_{\zeta}, E) \) as follows. We let \( D_\alpha \) and \( D_\zeta \) be two \( n \)-LCTs, and we have \( m \) \( l \)-LCTs that we denote with \( D_1, D_2, \ldots, D_m \), where \( l := \sqrt{n} \) and \( m := c\sqrt{n} \) for some natural number \( c \). We use the notation \( D_i \) for the corresponding \( k \)-LCT and its node set interchangeably. Their corresponding roots and leaf sets are denoted as \( r_\alpha, r_{\zeta}, r_1, r_2, \ldots, r_m \) and \( L_\alpha, L_{\zeta}, L_1, L_2, \ldots, L_m \) respectively, and with \( l_{X,1}, l_{X,2}, \ldots \) we enumerate the leaves of leaf set \( L_X \). Let \( C_\alpha = \{c_1, \ldots, c_m\} \) be an arbitrary \( m \)-sized subset of \( D_\alpha \)'s branch set \( B_\alpha \) for simplicity and in accordance to Figure 1 think of \( C_\alpha \) as the layer of nodes in \( B_\alpha \) that are at depth \( \log m \).

We let \( V_\zeta = D_\zeta \) and \( V_1 = \{r\} \cup D_\alpha \cup D_1 \cup \ldots \cup D_m \) and we add the following edges:

- Between \( r \) and \( D_\zeta \): We add one edge from \( r \) to \( r_{\zeta} \).
- Between \( r \) and \( D_\alpha \): For each \( j \in [m \log n] \) we add an edge from \( r \) to \( l_{\alpha,j} \).
- Between \( r \) and \( D_1, \ldots, D_m \): For each \( i \in [m] \) and \( j \in [\log n] \) we add an edge from \( r \) to \( l_{i,j} \).
- Between \( D_1, \ldots, D_m \) and \( D_\zeta \): For each \( i \in [m] \) we add one edge from \( r_i \) to \( r_{\zeta,i} \).
- Between \( D_1, \ldots, D_m \) and \( C_\alpha \): For each \( i \in [m] \) we add one edge from \( l_{i,j} \) to \( c_i \).

Note that the degree \( \text{deg}(r) \) is \( 2m \log n + 1 \) and that all the above defined edges add to any node in a LCT at most one edge that connects it to a node outside its own LCT.

The idea of the proof is the following: The graph is built in a way that information propagation from \( V_\zeta \) to \( V_1 \) is quick, but not the other way round. In the random \( \text{RPULL} \) model, wherever the rumor starts, it reaches \( r \) quickly and from there \( r_{\zeta} \) manages to get the rumor from \( r \) in polylogarithmic time. Then the rumor quickly propagates through \( V_\zeta = D_\zeta \), and from \( L_{\zeta} \) to all LCTs \( D_1, \ldots, D_m \) and afterwards to \( D_\alpha \).

In the adversarial \( \text{RPULL} \) model, as long as the rumor does not start in \( V_\zeta \), the rumor can quickly spread to \( r \), a few of the \( D_\alpha s \) and \( D_\zeta \) but not to \( V_1 \) because we let the adversary always prioritize a request at node \( r \) from a node in one of the \( D_\alpha s \) over a request from \( r_{\zeta} \) to prevent that \( r_{\zeta} \) will get the rumor. This is possible because we show that for polynomially many rounds there is always a request at \( r \) from one of the \( D_\alpha s \) to serve. Thus, to inform \( D_i \) all information must go through one of the edges \( \{r_i, l_{\zeta,i}\} \), \( i = 1, \ldots, m \), with \( r_i \) informed. In less than a polynomial number of rounds few enough of the \( r_i s \) are informed and in each round only few requests from the leaf nodes \( L_\zeta \) request from one of the \( r_i s \) at all making it unlikely that one of them requests from an informed \( r_i \). Hence propagation through one of these edges is unlikely and it takes a long time for the rumor to spread over the entire graph.

**Random** \( \text{RPULL} \). We start proving that random \( \text{RPULL} \) manages to spread the rumor quickly in \( G \).

1. If there is an informed node in \( D_\zeta \), by 2.4, w.h.p., all of \( D_\zeta \) is informed in \( O(\log n) \) rounds. Assume this has happened. Since each root of a LCT \( D_i \) has degree 3 in \( G \), it requests the rumor from an informed leaf node in \( L_\zeta \) w.c.p.– since no other node in \( L_\zeta \) is still uninformed and therefore able to create a conflict, w.h.p., in \( O(\log n) \) rounds, all root nodes \( r_1, \ldots, r_m \) know the rumor.

2. If there is an informed node in \( D_i \) for some \( i = 1, \ldots, m \), due to 2.4, the whole LCT \( D_i \) is informed w.h.p.(\( m \)) (=w.h.p.) within \( O(\log m) = O(\log n) \) rounds. Assume this has happened. Node \( c_i \in C_\alpha \) has degree at most 4 and therefore requests from its neighboring node \( l_{i,m} \) w.c.p., and since all nodes in \( D_i \) are informed, it will also get the rumor.

3. If there is an informed node in \( D_\alpha \), by 2.4, w.h.p., all of \( D_\alpha \) is informed in \( O(\log n) \) rounds. Assume this has happened. Almost half of all neighbors of \( r \) lie in \( L_\alpha \), and with same reasoning as above, \( r \) gets the rumor w.h.p. within \( O(\log n) \) rounds.

4. Let \( r \) be informed. All its neighbors in \( L_\alpha \) have degree \( n + 1 \) and therefore request with probability at most \( 1/n \) from \( r \), i.e., in expectation no more than 1 node from there requests the rumor from \( r \) each turn. Each neighboring leaf node in some \( L_i \) has degree \( m + 1 \), i.e., requests the rumor from \( r \) with probability at most \( 1/m \). Since \( r \) has \( m \log n \) such neighbors, in expectation no more than \( \log n \) such neighbors request from \( r \). With a Chernoff bound, w.h.p. there are no more than \( O(\log n) \) requests at \( r \). Since \( r_{\zeta} \) has degree 3, it therefore requests w.c.p. and gets the rumor with probability \( \Omega(1/\log n) \). W.h.p., the rumor is therefore propagated to \( r_{\zeta} \) in \( O(\log^2 n) \) rounds.
Altogether, wherever the source node is located, the above reasoning shows that, w.h.p., the rumor is propagated to all nodes within $O(\log^2 n)$ rounds.

**Adversarial RPULL.** Let $s \in V$ be the source node with the rumor. If $s \in D_i$ for some $i \in [m]$, then, without loss of generality, we assume that all nodes in $D_i$, $D_{\alpha}$ and $r$ are already informed, initially. Otherwise we inform all nodes in $D_{\alpha}$ and $r$. For $i \in [m]$ we call any $D_i$ informed, if it contains at least one informed node, otherwise uninformed.

The adversary has the following simple strategy. If $r_{\zeta}$ and at least one other node requests the rumor from $r$, then $r$ chooses to pass the rumor to any other node than $r_{\zeta}$. In every other aspect it follows an arbitrary strategy.

For time $t$ we denote with $X_t$ the number of informed LCTs $D_i$, and we assume without loss of generality that the corresponding LCTs are $D_1, \ldots, D_{X_t}$. Let $E_t$ be the event that in round $t$ no node in $D_{\zeta}$ has the rumor. Conditioning on this event implies that, by the structure of our graph and our model, nodes from $D_{\alpha}$ are uninformed node, otherwise informed.

Otherwise we inform all nodes in $D_{\zeta}$ and $r$. Then, without loss of generality, we assume that all nodes in $D_{\zeta}$ get the rumor from either $r$ or from $D_{\alpha}$, via connections $\{c_i, l_{i,m}\}$.

Let $X_t$ be the event that $X_t < 4ct + 2\log n$, $A_t$ the event that $r_{\zeta}$ gets the rumor in round $t$ and let $C_t$ be the event that a node from $L_{\zeta}$ gets the rumor from one of the roots $r_i$.

**Claim 2.5.** $P(X_t|E_t) \geq 1 - 1/n \geq e^{-1/n}$ for any $t \leq l/5c$.

In each round, $r$ can inform at most one node in a yet uninformed LCT $D_i$. Also, any uninformed node $l_{i,j}$ connects to its neighbor $c_i$ in $D_{\alpha}$ only with probability $1/(l + 1) < 1/l$. With at most $m$ such uninformed nodes trying to get the rumor from $D_{\alpha}$ each round, the amount of nodes $l_{i,j}, i = 1, \ldots, m$ informed through such an edge is upper bounded by a Binomial random variable Bin$(tcl, 1/l)$. Let $X'_t$ be the random variable that counts the number of times when an uninformed LCT $D_i$ gets informed through such an edge to $D_{\alpha}$ but not through a connection to $r$. Then, by Chernoff, for $\delta = (3 - \frac{1}{c}) + 2\frac{\log n}{ct} > 1$,

$$P(X_t \geq t + ct + \delta ct|E_t) \leq P(X'_t \geq (1 + \delta)ct) \leq \exp\left(-\frac{tc}{2}\delta \ln(1 + \delta)\right) \leq n^{-1}.$$ 

Therefore, w.h.p., $X_t$ is smaller than $4ct + 2\log n$ for $t \leq l/5c$. \hfill \Box

**Claim 2.6.** $P(A_{t+1}|E_t \cap X_t) \leq 1/n \leq 1 - e^{-1/n}$ for any $t \leq l/5c$.

Every uninformed node $l_{i,j} \in L_i$, where $j \in [\log n]$ and $i \in [m]$, requests from $r$ with probability $1/(l + 1)$. Choosing $c$ large enough $X_i$ implies that at least $m/2$ of the $D_i$s are uninformed. Thus there are at least $(m/2) \cdot \log n$ uninformed leaf nodes with a connection to $r$ in uninformed LCTs $D_i$. At least $0.4ct\log n$ such nodes request from $r$ in expectation. Choosing $c$ large enough, a simple Chernoff bound gives us that, w.h.p., at least one of these nodes requests from $r$. Consequently, w.h.p., $r$ does not give the rumor to $r_{\zeta}$ in round $t + 1$. \hfill \Box

**Claim 2.7.** $P(C_{t+1}|E_t \cap X_t) \leq 1 - e^{-\frac{1}{n}(2ct + \log n)}$ for any $t \leq l/5c$.

By our assumption of $E_t$, at the start of round $t + 1$, no node in $D_{\zeta}$ has the rumor, so for $C_{t+1}$ to possibly happen, a node from $L_{\zeta}$ must request from one of the nodes $r_1, \ldots, r_{X_t}$, which it does with probability $1/(n + 1) < 1/n$. The probability for $C_{t+1}$ to happen is therefore

$$P(C_{t+1}|E_t \cap X_t) \leq 1 - \left(1 - \frac{1}{n}\right)^{X_t} \leq 1 - \exp\left(-\frac{1}{n}(2ct + \log n)\right).$$ \hfill \Box
We know that $A_{t+1} \cup C_{t+1} \cap E_t \cap X_t \subseteq E_{t+1}$ since if under condition $E_t$ neither $A_{t+1}$ nor $C_{t+1}$ happens, then no node in $D_\zeta$ can get informed in round $t + 1$.

**Claim 2.8.** $P(E_t) \geq e^{-\frac{1}{n}(2ct^2 + t \log n)}$ for any $t \leq l/5c$.

The proof follows by induction. In round $t = 0$ clearly no node in $D_\zeta$ is informed, so the induction base holds. For the following, note that conditioned on $E_t$, events $A_{t+1}$ and $C_{t+1}$ (and therefore also their complements) are independent.

\[
P(E_{t+1}) \geq P(A_{t+1} \cup C_{t+1} \cap E_t \cap X_t) = P(E_t \cap X_t) P(A_{t+1} \cap C_{t+1} | E_t \cap X_t)
\]

\[
\geq P(E_t) P(X_t | E_t) P(A_{t+1} | E_t \cap X_t) P(C_{t+1} | E_t \cap X_t)
\]

\[
\geq \exp \left( -\left( \frac{1}{n}(2ct^2 + t \log n) + \frac{1}{n} + \frac{1}{n}(2ct + \log n) \right) \right)
\]

\[
\geq \exp \left( -\frac{1}{n}(2c(t + 1)^2 + (t + 1) \log n) \right)
\]

This means, that after $t = \sqrt{n/c}$ rounds with probability at least $e^{-3}$ still not all $\Theta(n)$ nodes in $G$ are informed, concluding the proof of Lemma 2.3.

**Theorem 2.9.** There is a graph $G = (V, E)$ of size $\Theta(n)$, such that for any $S_0 = \{s\} \subset V$:

- In expectation, the run-time of adversarial RPULL is in $\Omega(\sqrt{n})$.
- W.h.p., the run-time of randomized RPULL is in $O(\log^2 n)$.

**Proof.** Let $G'$ and $G''$ be duplicates of the graph $G$ from Lemma 2.3, $r'_\alpha$ and $r''_\alpha$ being the respective duplicates of $r_\alpha$. We set $G := G' \cup G''$ and add the edge $\{r'_\alpha, r''_\alpha\}$. Without loss of generality let $s \in V'$.

In the random version, the rumor propagates through all of $G''$ in $O(\log^2 n)$ rounds. Due to its low degree, $r''_\alpha$ gets the rumor from $r'_\alpha$ within $O(\log n)$ time after $G'$ is informed and again, in $O(\log^2 n)$ rounds $G''$ is informed completely.

In the adversarial version, $G''$ can only learn the rumor from $G'$ through edge $\{r'_\alpha, r''_\alpha\}$. But once $r''_\alpha$ knows the rumor, we can apply Lemma 2.3 again to prove that now progress is stalled.

\[
\square
\]

### 3 Comparison of PULL and RPULL

In this section we compare the two algorithms PULL and RPULL on general graphs. More precisely, we analyze how many rounds of RPULL are enough to cover the progress of one round of PULL. We manage to do so by coupling both algorithms. At the end of the section we head out to prove that this bound is tight.

#### 3.1 Dominance and Couplings

We begin with two examples of insufficient definitions of domination.

Showing for two algorithms $A$ and $A'$ that $P(u \in S^A) \geq P(u \in S^{A'})$ holds for all $u \in U$ is not enough to obtain a natural dominance definition of $A$ over $A'$, since for a set $M$ with $|M| > 1$ it might still be true that $P(M \subseteq S^A) < P(M \subseteq S^{A'})$.

Showing that $P(W \subseteq S^A) \geq P(W \subseteq S^{A'}) (*)$ holds for all $W \subseteq U$ is not enough either. Assume the following example: Let $U = \{a, b, c\}$ be the set of uninformed nodes. Assume that under $A$ the probability that the set of newly informed nodes equals $\{a, b, c\}$, $\{a\}$, $\{b\}$ or $\{c\}$ is $1/8 + \epsilon$ each and the probability that it equals one of the sets $\{a, b\}$, $\{a, c\}$, $\{b, c\}$ or $\emptyset$ is $1/8 - \epsilon$ each. Under $A'$ we inform any of those sets with probability $1/8$. Inequality (*) is fulfilled for any $W \subseteq U$, but the probability of the event “at least 2 nodes are informed” is by $2\epsilon$ smaller for $A$ than for $A'$. Hence, to cover most possibly arising cases, we use the definition of the so called (first order) stochastic dominance, which we present next.
Stochastic Dominance and Coupling

Let \( X_1 \) and \( X_2 \) be random variables with distributions \( P_1 \) and \( P_2 \) which take values in a finite (partially ordered) space \((S, \preceq_S)\) with a greatest element \( \top \), i.e., \( S \preceq_S \top \) for all \( S \in S \). A function \( f : S \rightarrow \mathbb{R} \) is called increasing if \( s_1 \preceq_S s_2 \) implies \( f(s_1) \leq f(s_2) \). The upper closure of a set \( W \subseteq S \) is defined as

\[
\text{cl} (W) = \{ W \in S \mid \exists X \in W, X \preceq_S W \}. \tag{1}
\]

**Definition 3.1** (Stochastic Dominance). We say that \( X_1 \) stochastically dominates \( X_2 \) if

\[
\forall W \subseteq S : P_1( X_1 \in \text{cl} (W)) \geq P_2( X_2 \in \text{cl} (W)) . \tag{2}
\]

**Definition 3.2** ((Monotone) Coupling). A coupling of \( X_1 \) and \( X_2 \) is a joint distribution \( \hat{P} \) of a random process \((\hat{X}_1, \hat{X}_2)\) taking values in \( S \times S \), such that its margins stochastically equal the distributions of \( X_1 \) and \( X_2 \) respectively, i.e.,

1. \( \sum_{A_2 \in S} \hat{P}( (\hat{X}_1, \hat{X}_2) = (A_1, A_2) ) = P_1( X_1 = A_1 ) \forall A_1 \in S \) and
2. \( \sum_{A_1 \in S} \hat{P}( (\hat{X}_1, \hat{X}_2) = (A_1, A_2) ) = P_2( X_2 = A_2 ) \forall A_2 \in S \) hold.

A coupling is called monotone (written \( X_1 \leq X_2 \)) if additionally the following holds:

\[
\forall A_1, A_2 \in S \text{ with } \hat{P}( (\hat{X}_1, \hat{X}_2) = (A_1, A_2) ) > 0 \text{ it follows that } A_1 \preceq_S A_2 . \tag{3}
\]

A coupling is called monotone w.h.p. (written \( X_1 \leq_{w.h.p.} X_2 \)) if for some \( c > 1 \) it satisfies the following

\[
\sum_{A_1 \not\preceq A_2} \hat{P}( (\hat{X}_1, \hat{X}_2) = (A_1, A_2) ) \leq \frac{1}{n^c} . \tag{4}
\]

In this paper we will set \( S = 2^U \), where \( U \subseteq V \) is the set of uninformed nodes and \( \preceq_S \) equals the subset relation on \( 2^U \). Colloquially speaking, having a monotone coupling between two processes means that the nodes, which get informed in one process, are a subset of the nodes which get informed in the other process.

The following theorem, Strassen’s Theorem [7,17], shows an equivalence between stochastic dominance and the notion of monotone couplings. \(^3\)

**Theorem 3.3** (Strassen). The following are equivalent:

1. \( X_1 \) stochastically dominates \( X_2 \),
2. There exists a monotone coupling between \( X_1 \) and \( X_2 \) such that \( X_1 \leq X_2 \),
3. \( \mathbb{E}(f(X_1)) \geq \mathbb{E}(f(X_2)) \), for all increasing functions \( f : S \rightarrow \mathbb{R} \).

We want to show that \( O(\frac{1}{\delta} \log n) \) rounds of RPULL stochastically dominate one round of PULL. This, however, is not possible as one can easily construct a graph in which some node \( u \) is informed with probability 1 in one round of RPULL, but with probability less than 1 in \( O(\frac{1}{\delta} \log n) \) rounds of RPULL.\(^4\) We therefore introduce the notion of highly probable stochastic dominance in analogy to the equivalencies from Strassen’s Theorem.

**Definition 3.4.** \( X_1 \) stochastically dominates \( X_2 \) with high probability, if there exists a coupling between \( X_1 \) and \( X_2 \) that is monotone with high probability.

If \( X_2 \) stochastically dominates \( X_1 \) we often write \( P( X_1 \subseteq X_2 ) = 1 \), and if \( X_2 \) stochastically dominates \( X_1 \) w.h.p., we write \( P( X_1 \subseteq X_2 ) \geq 1 - \frac{1}{n^c} \). Note that these notations always refer to a coupling between \( X_1 \) and \( X_2 \) and are colloquial formulations of (3) and (4).

---

\(^3\) The third equivalence in Strassen’s Theorem is added for an additional intuition of stochastic dominance; we do not use it.

\(^4\) Figure 2 in Appendix C can be easily used to verify this.
3.2 Coupling of PULL and RPULL

Theorem 3.5. W.h.p., for any set of informed nodes \( S \subseteq V \), \( T = O(\frac{\Delta}{\delta} \log n) \) rounds of RPULL stochastically dominate a single round of PULL.

Corollary 3.6. If in a graph \( G \) with initially informed nodes \( S \subseteq V \) the PULL algorithm informs all nodes in \( T \) rounds with probability \( p \), then the random RPULL algorithm informs all nodes in time \( O(\log n) \) with probability \((1-o(1))p\).

By PUSH – RPULL we denote the combination of RPULL with a simultaneous execution of the classic PUSH protocol. The restriction of a single node to answer only a limited number of requests does not limit the progress of the PUSH algorithm when disseminating a rumor. Hence we deduce the following corollary.

Corollary 3.7. W.h.p., for any set of informed nodes \( S \subseteq V \), \( T = O(\frac{\Delta}{\delta} \log n) \) rounds of PUSH – RPULL stochastically dominate a single round of PUSH – PULL.

To prove Theorem 3.5 we introduce a new algorithm VPULL (virtual pull), which we let run for at most \( T + 1 \) rounds and which, in any of those rounds, is strictly inferior to RPULL – except for some rare cases that, w.h.p., do not arise. Note that VPULL is only introduced as a tool to analyze the algorithm RPULL; hence difficulties/impossibilities that arise in an actual implementation of VPULL are not relevant.

The proof is then split into two parts:
1. W.h.p., \( T \) rounds of RPULL stochastically dominate \((T + 1)\) rounds of VPULL (Lemma 3.9),
2. \( (T + 1) \) rounds of VPULL stochastically dominate one round of PULL (Lemma 3.11).

Then Theorem 3.5 follows from the transitivity of the stochastical dominance relation.

By RPULL\(_T\) we denote the (randomized) process RPULL which runs for \( T \) rounds, by VPULL\(_{T+1}\) we denote the process VPULL which runs for \( T + 1 \) rounds and by PULL\(_T\) we denote the process PULL which runs for one round only. Random variables \( S_{T}^{\text{RPULL}} \), \( S_{T+1}^{\text{VPULL}} \) and \( S_{1}^{\text{PULL}} \) denote the respective sets of nodes that are informed after the corresponding number of rounds. RPULL\(_T\), VPULL\(_{T+1}\) and PULL\(_T\) are not completely characterized by the random variables \( S_{T}^{\text{RPULL}} \), \( S_{T+1}^{\text{VPULL}} \) and \( S_{1}^{\text{PULL}} \) – one has to include information about all requests and messages, that are sent by all nodes, to fully describe the random processes. Nevertheless, to show the desired result, it is sufficient to find a monotone coupling where condition (3) and (4), respectively, need to be fulfilled with regard to the subset relation of the set valued random variables \( S_{T}^{\text{RPULL}} \), \( S_{T+1}^{\text{VPULL}} \) and \( S_{1}^{\text{PULL}} \).

Definition of VPULL

Before we can state VPULL, we need a few definitions. An execution of VPULL consists of two phases. In the first phase nodes send tokens instead of the actual rumor and nodes who have received a token will be informed at the end of the first phase. In an execution of VPULL we let \( X_v(t) \) be the number of tokens which node \( v \) has sent up to round \( t \). In a specific round \( t \) denote with \( R_v(t) \) the set of nodes requesting from some informed node \( v \in S \) and with \( r_v(t) = \left| R_v(t) \right| \) its cardinality. \( R_v \), \( r_v \) and \( X_v \) are random variables which describe certain properties of an execution of VPULL, where large values of \( X_v \) or \( r_v \) indicate the unlikely case in which the monotonicity of the coupling might break.

Let us also define weakly connected nodes \( u \in U \) as nodes for which \( d_S(u)/d(u) \leq 1/2 \) and strongly connected otherwise. Let

\[ K = \Theta \left( \frac{\Delta}{\delta} + \log n \right), \quad T' = O \left( \frac{\Delta}{\delta} \log n \right) \quad \text{and} \quad T = \Theta(T'), \quad T \gg T' \]

Definition 3.8 (Good, Bad Execution). A \( T \)-round execution of VPULL is called a bad execution if for some \( v \in V \) or \( 1 \leq t \leq T \) it holds that \( X_v(t) > K \) or \( r_v(t) > K \), otherwise it is called a good execution.
We begin with an informal description of the algorithm and state the pseudocode afterwards. An execution of VPULL is split into two phases – the first phase consists of $T$ rounds and the second phase of one round. In the first phase an uninformed node requests the information uniformly at random from one of its neighbors and an informed node $v$ selects one of its incoming requests uniformly at random and sends a token to it with probability $\frac{1}{|\mathcal{F}|}$. Nodes, which get a token within those $T$ rounds, stop requesting from neighbors but do not forward any information to neighbors in consecutive rounds. At the end of round $T$ all nodes which have received a token are informed. In round $T + 1$ the limit to the number of requests that can be served by an informed node is stripped away. Then, in case of a bad execution all uninformed nodes perform one round of PULL, and in case of a good execution all uninformed strongly connected nodes perform one round of PULL. If we assume that tokens are as valuable as the information itself, in each of the first $T$ rounds, VPULL differs from RPULL only in the fact that the selected incoming connection is established with probability $\frac{1}{|\mathcal{F}|}$ whereas it is established deterministically in RPULL. For an uninformed node $u \in U$, that chooses to request a neighbor $v \in S$, this normalizes the probability to get a token to $1/T'$, independent of the amount of other requesting nodes. Except for round $T + 1$ this algorithm is clearly dominated by RPULL.

A formal definition is given by the following pseudocode where the parameters $K$ and $T'$ are defined as above. Note that the variables $X_v$, $R_v$, $\tau_v$, $BE_v$ and $BE$ can either be understood as random variables describing an execution of the VPULL algorithm or they can be updated directly in the algorithm as done below. Except for line 18 which uses global knowledge VPULL can be seen as a distributed algorithm.

**Coupling between RPULL and VPULL**

We generate first a coupling between RPULL and VPULL. In more layman terms imagine a (random) binary string $\sigma$ that contains all the information to generate either process in such a way that the informed nodes $S^{VPULL}_{T+1}$ are a subset of $S^{RPULL}_{T+1}$ for almost all strings $\sigma$; actually the probability that $\sigma$ is chosen in a way that $S^{VPULL}_{T+1}$ is not a subset of $S^{RPULL}_{T+1}$ is less than $n^{-c}$.

The coupling works in the following way. For each round $t \in \{1, \ldots, T + 1\}$ and each node $u$ we generate some random values $s_u(t)$, $s'_u(t)$ in $[0, 1]$. If $u$ is uninformed (in either algorithm) and has not received a token at the beginning of round $t$ then $s_u(t)$ is used to determine which neighbor $u$ contacts, otherwise (if $u$ is informed) $s_u(t)$ is used to select to which requesting node (if any) a token or the information, respectively, is handed over. In VPULL, $s'_u(t)$ is hereby used to determine whether $v$ does send out any message at all, confer line 13 from Algorithm 1. Clearly, a node $u$ that is provided with a token in VPULL in any round $t \leq T$ is then also informed in RPULL. For round $T + 1$ in VPULL the values $s_u(T + 1)$ are used to simulate one round of PULL for any node that is required to do so, as stated in the VPULL algorithm.

We claim that, w.h.p., $s_u(T + 1)$ is not used in the execution of VPULL for any node $u$ that does not get informed in $\text{VPULL}_T$. Which thus implies that, w.h.p., $S^{VPULL}_{T+1} \subseteq S^{RPULL}_{T+1}$, or in other words, $\text{RPULL}_T \geq_{w.h.p.} \text{VPULL}_{T+1}$.

**Lemma 3.9.** RPULL$_T$ stochastically dominates VPULL$_{T+1}$ with high probability.

**Proof.** We already argued why $S^{VPULL}_{T+1} \subseteq S^{RPULL}_{T+1}$ holds with probability 1. We now move on to prove that in round $T + 1$ of VPULL, w.h.p., no node is informed, that has not been informed in the first $T$ rounds of RPULL. For this consider round $T + 1$ of the VPULL algorithm. If neither ever any value $r_v$ nor any $X_v$ exceed $K$, then only strongly connected nodes simulate one round of PULL, but we claim that each strongly connected node has been informed in the first $T$ rounds of RPULL.

A strongly connected node $u \in U$ requests from an informed node $v \in S$ with probability at least $1/2$. In any given round due to Markov inequality with probability at least $1/2$ no more than $2\Delta/\delta$ nodes $u' \in U$ connect to $v$. The probability for $u$ to get informed under RPULL is thus at least $\frac{\delta}{8\Delta}$. Choosing
Algorithm 1 One \((T + 1)\)-round execution of \textsc{VPull}

\textbf{Input:} \(K\) – threshold for bad execution; \(T\) – parameter to normalize probabilities

\textbf{States:} informed/uninformed

\textbf{Oracle knowledge:} \(d_S(v)\) for every node \(v\); \(BE := \bigvee_{v \in V} BE_v\)

\textbf{Variables:}
- \(R_v\) set of nodes requesting from \(v\) in the corresponding round \((r_v := |R_v|)\)
- \(BE_v\) boolean indicator for bad execution caused at node \(v\)
- \(\text{tokenReceived}_v\) indicates whether a node will be informed after \(T\) rounds

1: \(BE_v \leftarrow \text{false}; \text{tokenReceived}_v \leftarrow \text{false}\)
2: \textbf{for} \(T\) rounds \textbf{do}
3: \hspace{1em} \textbf{switch state}_v \textbf{do}
4: \hspace{2em} \textbf{case uninformed}
5: \hspace{3em} \textbf{if} \(\text{tokenReceived}_v = \text{false}\) \textbf{then}
6: \hspace{4em} send request for rumor uniformly at random
7: \hspace{3em} \textbf{if} \(\text{msg} = \text{token}\) \textbf{then}
8: \hspace{4em} \text{tokenReceived}_v \leftarrow \text{true}
9: \hspace{3em} \textbf{case informed}
10: \hspace{4em} \textbf{if} \(r_v > K\) or \(X_v > K\) \textbf{then} \hspace{.5em} \text{// bad execution has been detected locally}
11: \hspace{4.5em} \(BE_v \leftarrow \text{true}\)
12: \hspace{4em} \textbf{else}
13: \hspace{5em} with probability \(r_v/T\) \textbf{do}
14: \hspace{6em} send \text{token} to uniformly at random chosen node in \(R_v \neq \emptyset\)
15: \hspace{5em} \(X_v \leftarrow X_v + 1\)
16: \hspace{3em} \textbf{if} \(\text{tokenReceived}_v = \text{true}\) \textbf{then}
17: \hspace{4em} \(\text{state}_v \leftarrow \text{informed}\) \hspace{.5em} \text{// node learns rumor}
18: \hspace{1em} \textbf{end switch}
19: \textbf{end for}

// Round \(T + 1\):
20: request \((BE, d_S(v))\) from global oracle
21: \textbf{if} \(BE = \text{true}\) \textbf{then} \hspace{.5em} \text{// bad execution has been detected globally}
22: \hspace{1em} execute one round of \textsc{Pull} \hspace{.5em} \text{// i.e., informed nodes inform all requesting neighbors}
23: \textbf{else if} \(d_S(v)/d(v) > 1/2\) \textbf{then} \hspace{.5em} \text{// node is strongly connected}
24: \hspace{1em} execute one round of \textsc{Pull}
25: \textbf{end if}

\(T = O\left(\frac{\Delta}{\delta} \log n\right)\) big enough and a union bound gives us that, w.h.p., all strongly connected nodes are informed in process \textsc{Pull}_T.

What remains to prove is that w.h.p. neither \(r(v)\) nor \(X(v)\) ever exceed \(K\) for any node \(v\) during the execution of \textsc{VPull}. Let \(1 < \kappa < c_{T,T'}\), be constants, \(K' := \frac{\Delta}{\delta} + \log n\) and \(K = c_{T,T'}K'\).

\textbf{W.h.p.,} \(r_v \leq K\) \textbf{in} \textsc{VPull}_T. \hspace{1em} \text{In expectation, no more than} \frac{\Delta}{\delta} \textbf{nodes can request from an informed node} \(v\). \hspace{1em} \text{Using a Chernoff bound for a single round and a single node,} \hspace{1em} \(P \left(r_v \geq \frac{\Delta}{\delta} + \kappa \log n\right) \leq n^{-\Theta(\kappa)}\) \textbf{holds.}

\textbf{W.h.p.,} \(X_v \leq K\) \textbf{in} \textsc{VPull}_T. \hspace{1em} \text{With a union bound over all nodes and all rounds and} \(\kappa\) large enough we obtain that, w.h.p., \(r_v\) never exceeds \(\kappa K'\) and therefore neither \(K\).

\textbf{W.h.p.,} \(X_v \leq K\) \textbf{in} \textsc{VPull}_T. \hspace{1em} \text{For} \(X_v\) \hspace{1em} \text{note that, w.h.p., in a single round no more than} \(\kappa K'\) \textbf{nodes request information from} \(v\). \hspace{1em} \text{And again a Chernoff bound gives us that} \(X_v\) \hspace{1em} \text{does not exceed} 2\kappa K' \frac{T}{T'} \text{with high probability. Choosing} c_{T,T'} = 2\kappa \frac{T}{T'} \text{concludes the proof.} \phantom{\square}

\textbf{Coupling between} \textsc{VPull} \textbf{and} \textsc{Pull}

In a single round of \textsc{Pull} a node \(u \in U\) is informed with probability \(d_S(u)/d(u)\), independently from which other nodes are informed. For \(T + 1\) rounds of \textsc{VPull} we can show that a node is informed at least with the same probability and independently from which other nodes get informed, as claimed in the next
lemma. Afterwards we prove that this is sufficient to deduce the requirements of Theorem 3.3 and hence the dominance of VPULL_{T+1} over PULL_1.

For \( u \in U \) let \( C_u \) be the set of all possible conditions saying which nodes in \( N(S) \) other than \( u \) are and are not informed under VPULL_{T+1}, i.e., conditions of the type \( v \in S^{VPULL}_T \) or \( v \notin S^{VPULL}_{T+1} \) for \( v \in N(S) \).

**Lemma 3.10.** In VPULL_{T+1} a node \( u \in U \) is informed at least with probability \( \frac{d_S(u)}{d(u)} \), independently from which other nodes are informed, i.e., for all \( u \in U \) and for all sets of conditions \( I \subseteq C_u \) with \( P(I) > 0 \):

\[
P \left( u \in S^{VPULL}_{T+1} \ \big| \ I \right) \geq \frac{d_S(u)}{d(u)}.
\]

**Proof.** If \( u \in U \) is strongly connected, the result holds because VPULL executes at least one round of PULL for \( u \) if \( u \) did not get informed after \( T \) rounds. In a bad execution, VPULL executes one round of PULL for any uninformed node and the claim holds trivially. Thus assume that \( u \) is weakly connected and we are in a good execution. Let \( s = d_S(u) \) and \( N_S(u) = \{v_1, \ldots, v_s\} \) be the neighbors of \( u \) in \( S \). We call a node \( v \in N_S(u) \) busy in round \( t \) if it informs some node other than \( u \). Let \( y_t \) be the number of busy nodes in round \( t \). In a good execution (which we denote by \( G \)), any node in \( N_S(u) \) can inform at most \( K \) nodes and hence there is the following constraint on the sum of all \( y_t \)'s

\[
\sum_{t=1}^{T} y_t \leq s \cdot K.
\]

We can ignore conditions in \( I \) corresponding to nodes which do not have a common neighbor from \( N_S(u) \) with \( u \) because in our computation we assume that \( u \) can only get the rumor through \( S \). The only effect on \( u \) by the conditions in \( I \) can be captured by the number of busy nodes. However, since the number of nodes which are informed per node in a good execution is small compared with \( T \), there are sufficiently many rounds with sufficiently many non-busy nodes to inform \( u \). More precisely, if \( u \) requests from a non-busy node it is informed at least with probability \( \frac{1}{T} \). Thus, the probability that \( u \), conditioned on \( I \wedge G \) with \( P(I \wedge G) > 0 \), is not informed is smaller or equal to (with \( c = T/T' \))

\[
\prod_{t=1}^{T} \left( 1 - \frac{s - y_t}{d(u) \cdot T'} \right) \leq \left( 1 - \frac{s}{d(u) \cdot T'} \right)^T \leq e^{-c(1 - \frac{K}{T}) \frac{1}{d(u)}} \leq 1 - \frac{d_S(u)}{d(u)}.
\]

The first inequality holds because under constraint (6) the expression on the left hand side is maximized for \( y_t = \frac{s \cdot K}{d(u)} \). The last inequality holds due to \( \frac{s}{d(u)} \leq 1/2 \), \( c(1 - K/T) \geq 2 \) and the fact that \( e^{-2x} \leq 1 - x \) for any \( x \in [0, 1/2] \).

**Lemma 3.11.** VPULL_{T+1} stochastically dominates PULL_1.

**Proof.** We show that the requirements of Definition 3.1, (2), follow from Lemma 3.10.

In this proof we use the closure \( cl(\mathcal{W}) \), defined in (1), for different spaces \( S \). For \( U' \subseteq U \) we write \( cl_{U'}(\mathcal{W}) \) to indicate that \( S = 2^{U'} \) in terms of (1).

Let \( U \) be partitioned into \( A \subseteq U \) and \( U' \subseteq U \), that is \( A = U \cup U' \) with \( A \cap U' = \emptyset \). Let \( \mathcal{W}' \subseteq 2^{U'} \) and \( E_A \) be a set of conditions of the type \( u \in S^{VPULL}_{T+1} \) or \( u \notin S^{VPULL}_{T+1} \), for all \( u \in A \). Consider the following inequality

\[
P \left( S^{VPULL}_{T+1} \wedge A \in cl_{U'}(\mathcal{W}') \ \big| \ E_A \right) \geq P \left( S^{PULL}_{T+1} \wedge A \in cl_{U'}(\mathcal{W}') \right).
\]

Note that if \( |A| = |U| - 1 \) and hence \( |U'| = 1 \), condition (7) will equal condition (5) in Lemma 3.10, i.e., our proven precondition. If \( A = \emptyset \), condition (7) will be equal to condition (2) of Definition 3.1, i.e., what we want to prove.
By induction on the size of $U'$ we show that (7) holds for all partitions of $U$ into sets $A$ and $U'$. The induction start consists of all $U'$ and $A$ with $|U'| = 1$ and $|A| = |U| - 1$; it follows directly from Lemma 3.10. Assume that the induction hypothesis holds for all $U'$ with $|U'| = k$. Now consider a partition of $U$ into $A$ and $U'$ with $|U'| = k + 1$. Let $x \in U'$ be arbitrary and fix the following notation.

$$U'' = U \setminus \{x\},$$

$$W'' = \{W \setminus \{x\} \mid W \in W'\} \subseteq 2^{U''},$$

$$W''' = \{W \in W' \mid x \notin W\} \subseteq 2^{U''}.$$

$$P\left(S_{T+1}^{\text{VPULL}} \setminus A \in \text{cl}_{U'}(W') \mid E_A\right)$$

$$= P\left(x \in S_{T+1}^{\text{VPULL}}\right) P\left(S_{T+1}^{\text{VPULL}} \setminus A \in \text{cl}_{U'}(W') \mid E_A \cap x \in S_{T+1}^{\text{VPULL}}\right)$$

$$+ P\left(x \notin S_{T+1}^{\text{VPULL}}\right) P\left(S_{T+1}^{\text{VPULL}} \setminus A \in \text{cl}_{U'}(W') \mid E_A \cap x \notin S_{T+1}^{\text{VPULL}}\right)$$

$$\stackrel{(*)}{=} P\left(x \in S_{T+1}^{\text{VPULL}}\right) P\left(S_{T+1}^{\text{VPULL}} \setminus (A \cup \{x\}) \in \text{cl}_{U''}(W''') \mid E_A \cap x \notin S_{T+1}^{\text{VPULL}}\right)$$

$$+ P\left(x \notin S_{T+1}^{\text{VPULL}}\right) P\left(S_{T+1}^{\text{VPULL}} \setminus (A \cup \{x\}) \in \text{cl}_{U''}(W''') \mid E_A \cap x \notin S_{T+1}^{\text{VPULL}}\right)$$

$$\geq P\left(x \in S_{T+1}^{\text{VPULL}}\right) P\left(S_{T+1}^{\text{VPULL}} \setminus (A \cup \{x\}) \in \text{cl}_{U''}(W''')\right)$$

$$+ P\left(x \notin S_{T+1}^{\text{VPULL}}\right) P\left(S_{T+1}^{\text{VPULL}} \setminus (A \cup \{x\}) \in \text{cl}_{U''}(W''')\right)$$

Note that $W''' \subseteq W''$ and hence $\text{cl}_{U''}(W'') \subseteq \text{cl}_{U''}(W''')$. Thus we obtain

$$\geq P\left(x \in S_{T+1}^{\text{VPULL}}\right) P\left(S_{T+1}^{\text{VPULL}} \setminus (A \cup \{x\}) \in \text{cl}_{U''}(W''')\right)$$

The proof correctness relies on the fact that $P(A \cap B) = P(A \cap B \mid B)$ for events $A$ and $B$. More precisely, every elementary event in $\{S_{T+1}^{\text{VPULL}} \setminus A \in \text{cl}_{U'}(W')\} \cap E_A \cap \{x \in S_{T+1}^{\text{VPULL}}\}$ is in a direct correspondence to an elementary event in $\{S_{T+1}^{\text{VPULL}} \setminus (A \cup \{x\}) \in \text{cl}_{U''}(W''')\} \cap E_A \cap \{x \in S_{T+1}^{\text{VPULL}}\}$ and vice versa. The same holds for the probabilities which use the condition $x \notin S_{T+1}^{\text{VPULL}}$.

**Proof of Theorem 3.5.** The proof is a direct combination of Lemma 3.9 and Lemma 3.11. □

### 3.3 The Round-by-Round Analysis is Tight

**Lemma 3.12.** The time bound $T = O(\frac{n}{\delta} \log n)$ from Theorem 3.5 is tight.

**Proof.** In order for $T$ rounds of RPULL to quasi-dominate 1 round of PULL, any node $v$ must get informed in $T$ rounds of RPULL with at least the same probability as within one round of PULL (or w.h.p., if the latter probability equals one). We construct a graph $G$ for which at least $T = \Omega(\frac{n}{\delta} \log n)$ rounds of RPULL are necessary to guarantee this picture. A picture depicting the graph can be found in Appendix C.

We partition set $V$ into $V = A \cup B \cup T_{1,1} \cup \ldots \cup T_{k_2,k_2}$, where $A = \{a_1, \ldots, a_{k_2}\}$, $B = \{b_1, \ldots, b_{k_2}\}$ and $k = n^{1/5}$. $A$ and $B$ form a complete bipartite graph with edges running between $A$ and $B$. For each
$j \in [k^2]$, node $b_i$ is connected to one node $t_{i,j} \in T_{i,j}$. Each $T_{i,j}$ forms a complete graph of size $k$. In this graph, $\delta = k - 1$ (acquired in $T_{i,j}$) and $\Delta = 2k^2$ (nodes in $B$), and therefore $\Delta/\delta \in \Theta(k)$. The total size of the graph is $|V| = n + o(n)$. Initially, we let $S_0 = B$.

In this graph, within one round of PULL, all nodes of $A$ are informed with probability 1.

Now consider the same graph after $m \leq k^2/2$ rounds of RPULL and let us assume that some node $a \in A$ is still uninformed. It requests in this round from some node $b_i$. Let $X_i$ be the number of requests at $b_i$.

Within $m$ rounds, each node $b_i$ managed to inform at most $m$ of its neighbors from $NB_i := \{t_{i,1}, \ldots, t_{i,m}\}$. Since $m \leq k^2/2$, at least half of all nodes in $NB_i$ are still uninformed and thus, they have degree $k$, $E[X_i] \geq k/2$. Applying Chernoff, we get that w.h.p., $X_i \geq k/4$. In this scenario for $a$ the probability to be chosen over one of its competitors is at most $4/k$, regardless of $m$, and therefore, $P(a \in S^R_{m\text{PULL}}) \leq 1 - \left(\frac{4}{k}\right)^m$. For this to exceed $1 - 1/n$, $m$ has to be in $\Theta(\frac{\Delta}{\delta} \log n)$.

\[ \square \]

4 Conclusions

Lemma 3.12 and Theorem 3.5 show that to simulate one round of PULL, $\Theta(\frac{\Delta}{\delta} \log n)$ rounds of RPULL are required. However, in case one wants stochastical dominance (w.h.p.) over $T > 1$ rounds of PULL, the lower bound proof of Lemma 3.12 does not hold anymore. We believe that for $T = \Omega(\log n)$, on any graph $G$ and any set of initially informed nodes $S \subseteq V$, $O(T(\frac{\Delta}{\delta} + \log n))$ or maybe even $O(T(\frac{\Delta}{\delta}) + \log n)$ rounds of RPULL suffice to stochastically dominate $T$ rounds of PULL. That proving this assumption might be a challenging task is underlined by a similar conjecture in [1], in which the authors do a coupling of synchronous and asynchronous PUSH-PULL. They obtain a similar multiplicative $O(\log n)$ factor and also conjecture that it can be improved to an additive $O(\log n)$ term.

A possible alternative restriction of the PUSH-PULL protocol could be given by the following algorithm. In each round, every node requests from an outgoing neighbor chosen uniformly at random. At each node, one of the incoming requests is chosen (e.g., uniformly at random) and a connection to the requesting node is established. Finally, over all established links between an informed and an uninformd node, the uninformed node learns the rumor. Note that unlike in the restricted PUSH-PULL variant described in our paper, here, also two informed nodes or two uninformed nodes could be paired. Such a PUSH-PULL variant can be analyzed in an analogous way to our analysis of the RPULL protocol and it can be shown that $O(\frac{\Delta}{\delta} \log n)$ rounds of this algorithm stochastically dominate a single round of the regular PUSH-PULL protocol.

Appendices

A Chernoff Statement for Lemma 2.2

Lemma A.1. Let $X_1, X_2, \ldots, X_n$ be independent geometric random variables with $X_i \sim Geo(p_i)$ for $i = 1, \ldots, n$ and $0 < p_1 \leq p_2 \leq \ldots < 1$. Let $X = \sum_{i=1}^{n} X_i$. Then

$$P(X > 3(\mu + t)) \leq e^{-\frac{p_1}{2}\mu - p_1 t}. \quad (8)$$

Proof. Let $\gamma = -\ln(1 - \frac{p_1}{3}) > 0$. Because of $p_1 \leq p_i$ this implies $e^\gamma \cdot (1 - p_i) < 1$ for all $i = 1, \ldots, n$. We need this condition at (*) in the proof of the following claim.

Claim 1: $E[e^{\gamma X_i}] \leq 1 + \frac{p_1}{2p_i}$.

Proof of Claim 1. With a straightforward calculation one obtains

$$E[e^{\gamma X_i}] = \sum_{k=1}^{\infty} P(X_i = k) e^\gamma = p_i e^\gamma \sum_{k=1}^{\infty} ((1 - p_i) e^\gamma)^{k-1} \quad (*)$$

$$= \frac{p_i e^\gamma}{1 - (1 - p_i) e^\gamma} = \frac{p_i}{e^{-\gamma} - 1 + p_i}$$

$$= 1 + \frac{1 - e^{-\gamma}}{e^{-\gamma} + p_i - 1} = 1 + \frac{1 - (1 - \frac{p_1}{3})}{1 - \frac{p_1}{3} + p_i - 1}$$

$$= 1 + \frac{\frac{p_1}{3}}{p_i - \frac{p_1}{3}} \leq 1 + \frac{p_1}{2p_i}. \quad \Box$$

Now we can show the actual result. Since $x \mapsto e^{\gamma x}$ is an increasing function for $\gamma > 0$ we obtain

$$P(X > 3(\mu + t)) = P(e^{\gamma X} > e^{\gamma(\mu + t)}) \quad \text{(Markov)}$$

$$\leq e^{-3\gamma(\mu + t)} \prod_{i=1}^{n} E[e^{\gamma X_i}] \quad \text{(claim 1)}$$

$$\leq e^{-3\gamma(\mu + t)} \prod_{i=1}^{n} \left(1 + \frac{p_1}{2p_i}\right) \quad (1 + x \leq e^x, x \in \mathbb{R})$$

$$\leq \left(1 - \frac{p_1}{3}\right)^{3(\mu + t)} e^{\sum_{i=1}^{n} \frac{p_1}{2p_i}} \quad \left(\mu = \sum_{i=1}^{n} \frac{1}{p_i}\right)$$

$$= \left(1 - \frac{p_1}{3}\right)^{3(\mu + t)} (e^{\frac{p_1}{2}\mu}) \quad (1 - x \leq e^{-x}, x \in \mathbb{R})$$

$$\leq e^{p_1(\mu + t) + \frac{p_1}{2}\mu} = e^{-\frac{p_1}{2}\mu - p_1 t}. \quad \Box$$
B Proofs

Claim B.1. In the setting of Lemma 3.11 the following equalities hold

\[ P\left( S^\text{VPULL}_{T+1} \setminus A \in \text{cl}_{U'}(W') \mid \mathcal{E}_A \cap x \in S^\text{VPULL}_{T+1} \right) = P\left( S^\text{VPULL}_{T+1} \setminus (A \cup \{x\}) \in \text{cl}_{U''}(W'') \mid \mathcal{E}_A \cap x \in S^\text{VPULL}_{T+1} \right) \]

and

\[ P\left( S^\text{VPULL}_{T+1} \setminus A \in \text{cl}_{U'}(W') \mid \mathcal{E}_A \cap x \notin S^\text{VPULL}_{T+1} \right) = P\left( S^\text{VPULL}_{T+1} \setminus (A \cup \{x\}) \in \text{cl}_{U''}(W'') \mid \mathcal{E}_A \cap x \notin S^\text{VPULL}_{T+1} \right). \]

Proof. We prove that the left hand side of the first inequality is smaller or equal to the right hand side of the first equality. The proof for the reverse inequality and both proofs for the second equation are along similar lines and omitted. The prove relies on the fact that \( P(A \mid B) = P(A \cap B \mid B) \) for events \( A \) and \( B \). Therefore we show that every elementary event in

\[ \left\{ S^\text{VPULL}_{T+1} \setminus A \in \text{cl}_{U'}(W') \right\} \cap \mathcal{E}_A \cap \left\{ x \in S^\text{VPULL}_{T+1} \right\} \]

is in a direct correspondence to an elementary event in

\[ \left\{ S^\text{VPULL}_{T+1} \setminus (A \cup \{x\}) \in \text{cl}_{U''}(W'') \right\} \cap \mathcal{E}_A \cap \left\{ x \in S^\text{VPULL}_{T+1} \right\} \]

and vice versa.

Let \( E \) be an elementary event in (9). Because \( E \) is a subset of \( U = U' \cup A \) we can write \( E \) as disjoint union of \( E_1 \subseteq U' \) and \( E_2 \subseteq A \), with the following properties

\((x \in E_1)\) which follows because \( E \) satisfies \( \left\{ x \in S^\text{VPULL}_{T+1} \right\} \),

\((E_2 \text{ fulfills } \mathcal{E}_A)\) which follows because \( E \) satisfies \( (\mathcal{E}_A) \),

\((\exists W \in W' \text{ s.t. } W \subseteq E_1)\) which follows because \( E \) satisfies \( \left\{ S^\text{VPULL}_{T+1} \setminus A \in \text{cl}_{U'}(W') \right\} \). \hspace{1cm} (11)

Now define \( \hat{E}_1 = E_1 \setminus \{x\} \), \( \hat{E}_2 = E_2 \cup \{x\} \) and \( \hat{E} = \hat{E}_1 \cup \hat{E}_2 \). Then the following hold

\[ \left( x \in \hat{E}_2 \right) \text{ thus } \hat{E} \text{ satisfies } \left\{ x \in S^\text{VPULL}_{T+1} \right\}, \]

\[ \left( \hat{E}_2 \text{ fulfills } \mathcal{E}_A \right) \text{ thus } \hat{E} \text{ satisfies } (\mathcal{E}_A). \]

Let \( W \in W' \) be such that it satisfies (11), i.e., \( W \subseteq E_1 \). Define \( \hat{W} = W \setminus \{x\} \), then \( \hat{W} \in W'' \) and \( \hat{W} \subseteq \hat{E}_1 \) holds. Thus \( \hat{E} \) satisfies \( \left\{ S^\text{VPULL}_{T+1} \setminus (A \cup \{x\}) \in \text{cl}_{U''}(W'') \right\} \).

Altogether we conclude that \( \hat{E} \) is an elementary event in (10) and the correspondence is one to one. \( \square \)

C Pictures

C.1 Picture for Lemma 2.3, Figure 1

In random RPULL the node \( r_\zeta \) learns the rumor within \( O(\log^2 n) \) rounds and can spread the information through the graph in polylogarithmic time.

In adversarial RPULL the adversary prevents \( r_\zeta \) from learning the rumor by always disseminating the rumor to one of the requesting nodes of in \( D_1, \ldots, D_m \) in every round. We can show that the number of informed \( D_i \)s grows slowly and hence such requests exist w.h.p. as long as no node in \( D_\zeta \) is informed. Also, with only few \( D_i \)s informed, due to their high degrees, leaf nodes in \( L_\zeta \) are unlikely to request from a \( D_i \) containing the rumor, and hence the progress of rumor propagation is stalled.
Figure 1: Picture for Lemma 2.3, proving that random and adversarial RPULL have exponentially different running times on general graphs. Grey areas indicate fully connected parts of the graph.

Figure 2: Picture for Lemma 3.12, proving that $\Omega(\frac{\Delta}{\delta} \log n)$ rounds of RPULL are necessary to simulate one round of PULL.
C.2 Picture for Lemma 3.12, Figure 2

All not filled circular nodes in the bipartite graph in the top \((B)\) have the rumor at the start of the execution. In one round of \(PULL\) all filled nodes in the bipartite graph \((A)\) learn the rumor with probability one. In random \(RPULL\ \Omega(\frac{\Delta}{\delta} \log n)\) rounds are necessary to inform these nodes, because for each of the nodes in \(A\) the probability to be informed in one round of \(RPULL\) is in \(\Theta(1/k)\). This is due to the high number of requests from nodes in \(T_{i,j}\) each round to the informed nodes in \(B\).
