Abstract. Effects of ethephon, AgNO₃, and AVG on formation of embryogenic callus and somatic embryogenesis were examined in cultures of explants of spinach (Spinacia oleracea L. ‘Nippon’) roots. At 10 μM, ethephon more than doubled the frequency of formation of embryogenic callus as compared to that in cultures without ethephon. Silver nitrate at 10 μM and AVG at 1 μM each inhibited formation of embryogenic callus but neither reduced the growth rate of established callus. When ethephon was applied at 10 μM during embryogenesis, it completely inhibited embryo development. By contrast, AgNO₃, at 10 μM markedly increased the number of embryos. Results suggest that ethylene might be essential as a plant hormone for formation of embryogenic callus but inhibits somatic embryogenesis per se in cultures of explants of spinach roots. Chemical names used: 2-chloroethylphosphonic acid (ethephon), silver nitrate (AgNO₃), aminoethoxyvinylglycine (AVG).

Ethylene is a plant hormone involved in the regulation of various aspects of plant growth and differentiation. Many studies have been published on the effects of this compound on organogenesis and somatic embryogenesis in plant tissue cultures (Krikorian 1995).

There have been numerous reports demonstrating that exogenously supplied ethylene inhibits somatic embryogenesis and some ethylene inhibitors have been shown to have a promotive effect. For example, addition of ethylene or of the ethylene-producing compound ethephon prevents embryogenesis in carrot (Daucus carota L.) (Tisserat and Murashige 1977, Wochok and Wetherell 1971), while AgNO₃, a potent inhibitor of the actions of ethylene (Beyer 1976), enhances production of embryogenic callus with a typical friable texture in corn (Zea mays L.) (Songstad et al. 1991, Vain et al. 1989), as well as embryogenesis in carrot (Roustan et al. 1990). Furthermore, inhibitors of ethylene biosynthesis, such as AVG and cobalt ions, stimulate somatic embryogenesis in white spruce (Picea glauca (Moench) Voss) (Kong and Yeung 1994) and in certain genotypes of soybean [Glycine max (L.) Merrill] with limited regenerative ability (Santos et al. 1997).

It has also been demonstrated that application of ethylene promotes somatic embryogenesis. For example, in orange [Citrus sinensis (L.) Osbeck], a low concentration of ethephon (0.1 mg·L⁻¹) greatly enhances embryogenesis (Kochba et al. 1978) and in alfalfa (Medicago sativa L.), ethylene is required both for callus growth and for somatic embryogenesis (Kepczynski et al. 1992). In coffee (Coffea canephora Pierre ex Froehn.), somatic embryogenesis is inhibited by ethylene inhibitors and enhanced by exogenous gaseous ethylene (Hatanaka et al. 1995). These results are apparently contradictory, but they demonstrate that the effects of ethylene and of ethylene inhibitors on somatic embryogenesis differ among plant species and among various types of tissues.

Somatic embryogenesis of spinach (Spinacia oleracea) was first reported by Xiao and Branchard (1993), and a protocol for regeneration of plants from root explants was established subsequently by Komai et al. (1996a, 1996b, 1996c). Tests of effects of various nutritional and hormonal supplements revealed that application of gibberellic acid (GA₃) in combination with a relatively low concentration of fructose (29 mM) was beneficial for formation of embryogenic callus in cultures of root explants (Komai et al. 1996a, 1996c). However, the effects of exogenous ethylene on embryogenesis remained to be investigated.

The following research was conducted to characterize the role of ethylene in somatic embryogenesis in spinach with the goal of improving the efficiency of regeneration of plants from root explants. Effects of ethephon, AgNO₃, and AVG on formation of embryogenic callus and somatic embryogenesis using established cultures of root explants from spinach seedlings were investigated (Komai et al. 1996a).

Materials and Methods

Plant material. Root explants were prepared from aseptically grown seedlings of ‘Nippon’ spinach as follows. Seeds were surface sterilized by dipping them in 70% (v/v) ethanol for 30 s and then soaking them for 1 h in a solution of 10% sodium hypochlorite (active chlorine, 1%) that contained 0.1% polyoxyethylene sorbitan monolaurate (Tween 20). The seeds were rinsed with sterile distilled water and then placed in glass jars (60 mm in diameter × 110 mm in height) containing 25 mL of semisolid medium that contained half-strength Murashige and Skoog (MS) salts (Murashige and Skoog 1962), complete MS vitamins, sucrose at 20 g·L⁻¹, and agar at 7 g·L⁻¹ (pH 5.7). The seeds were incubated at 25 °C in darkness. Ten to fourteen days later, root explants =5 mm in length were excised from the seedlings.

Callus induction. For induction of callus the protocol of Komai et al. (1996a) was used with minor modification. Root
explants were placed in a 100 mL Erlenmeyer flask containing 20 mL of callus-induction (CI) medium, consisting of half-strength MS salts, complete MS vitamins, fructose at 5.4 g·L⁻¹, and 10 µM 1-naphthaleneacetic acid (NAA), and 0.1 µM gibberellic acid (GA₃). The medium was adjusted to pH 5.7 with 0.1 mol·L⁻¹ HCl and solidified with agar at 7 g·L⁻¹. To examine the effects of ethylene on formation of embryogenic callus, ethephon (Wako Pure Chemical Co., Osaka, Japan), AgNO₃, and AVG (Sigma, St. Louis, Mo.) were added to the CI medium. Ethephon and AgNO₃ were added at 0, 1, 10, or 100 µM, while AVG was added at 0, 1, or 10 µM. Ethephon and AVG were filter-sterilized and added to the medium after the medium autoclaved. Cultures were incubated at 25 °C with a 16-h photoperiod of 70 µmol·m⁻²·s⁻¹ from fluorescent lamps (FLR40SW/M/36; Mitsubishi Osram, Yokohama, Japan). To estimate callus growth, fresh weights of calli were recorded after 4 weeks.

ESTIMATING THE FREQUENCY OF EMBRYOGENIC CALLUS FORMATION. After root explants had been cultured 4 weeks on CI medium, the embryogenic capacity of each callus was examined by transferring entire explants with developing calli to a 100 mL Erlenmeyer flask containing 20 mL of embry-production (EP) medium consisting of half-strength MS salts, MS vitamins, sucrose at 20 g·L⁻¹, and agar at 7 g·L⁻¹ (pH 5.7). The percentage of calli that formed embryos was recorded 4 weeks later. In this report we refer to callus as embryogenic callus that would eventually develop somatic embryos on a medium without growth regulators. Since more than 90% of embryos had developed to the late torpedo stage or formed young seedlings by the time we examined the cultures, embryogenic calli were easily distinguished by their appearance from calli that had only increased in size.

RESULTS

EFFECTS OF ETHYLENE AND ETHYLENE INHIBITORS ON SOMATIC EMBRYOGENESIS. Embryogenic callus was obtained by culturing explants of spinach roots on CI medium for 4 weeks. To examine the effects of ethylene on somatic embryogenesis, we cultured these calli in a 100 mL Erlenmeyer flask containing 20 mL of EP medium supplemented with ethephon or AgNO₃ at 0, 1, 10, or 100 µM. Ethephon was filter-sterilized and added to the autoclaved medium just before the medium began to solidify. Cultures were incubated at 25 °C with a 16-h photoperiod of 70 µmol·m⁻²·s⁻¹ from fluorescent lamps. Four weeks after transfer of calli to EP medium, we determined the number of embryos that had formed by dispersing calli in water using forceps. Embryos were counted directly or under a dissecting microscope. The percentages of calli that had differentiated embryos were also calculated.

EXPERIMENTAL DESIGN AND STATISTICAL ANALYSIS. Five pieces of root explants and callus tissues were transferred to test media in each culture vessel. Each treatment consisted of 25 explants and each experiment was repeated three to five times. Means and standard errors were calculated based on the data obtained from repeated experiments.

Fig. 1. Typical appearance of embryogenic callus derived from explants of spinach roots and of developing somatic embryos on embryogenic callus. (A) Callus formed on medium that contained 10 µM NAA and 0.1 µM GA₃. (B) Somatic embryos differentiated from callus on medium without growth regulators. (C) Suppression of embryogenesis from embryogenic callus after transfer to medium that contained 10 µM ethephon. (D) Enhanced embryogenesis from embryogenic callus after transfer to medium that contained 10 µM AgNO₃. Bars: A and C = 2 mm; B and D = 5 mm.

Fig. 2. Effects of ethephon on the formation of embryogenic callus from explants of spinach roots. Explants were cultured for 4 weeks on the medium that contained 10 µM NAA with or without 0.1 µM GA₃ and supplemented with ethephon at 0 to 100 µM. Calli were then transferred to medium without growth regulators for identification of embryogenic callus. Embryogenic callus was identified after 4 weeks culture. Vertical bars represent ± 1 se. (n = 3).
hon had little promotive effect in the absence of GA$_3$ but, in the presence of 0.1 µM GA$_3$, it stimulated considerable formation of embryogenic callus (Fig. 2). All calli were very friable, regardless of the presence or absence of GA$_3$, and application of ethephon had no effect on the appearance of calli. The most effective concentration of ethephon for formation of embryogenic callus was 10 µM but no inhibition was observed at a higher concentration (Fig. 2). Finally, more than four times as many somatic embryos developed from callus formed on medium that contained 10 µM ethephon than regenerated from callus grown without ethephon (data not presented).

**EFFECTS OF AgNO$_3$ AND AVG ON EMBRYOGENIC CALLUS FORMATION.** At 10 µM, AgNO$_3$ completely suppressed development of embryogenic callus, whereas it more than doubled the rate of callus growth. At higher concentrations, AgNO$_3$ suppressed embryogenesis and reduced the growth rate of callus (Table 1), possible because of the toxicity of the metal ions. AVG almost completely inhibited formation of embryogenic callus at 1 µM (Table 1). The inhibitory effect of 1 µM AVG on the formation of embryogenic callus was reversed up to 76% by application of ethephon at 10 µM. No significant reductions in the rate of callus growth were recognized over the range of AVG concentrations tested.

**EFFECTS OF ETHEPHON AND AgNO$_3$ ON EMBRYOGENESIS FROM CALLI.** In contrast to the promotive effects of ethephon on the formation of embryogenic callus, addition of ethephon to EP medium strongly inhibited differentiation of embryos from calli (Figs. 1C and 3), and at 100 µM no differentiation was observed at all. Concomitantly, the percentage of calli showing evidence of embryogenesis was reduced by application of ethephon. In accordance with these observations, AgNO$_3$ at concentrations up to 10 µM markedly increased the numbers of embryos that developed from embryogenic calli (Figs. 1D and 3). Addition of 10 µM AgNO$_3$ to EP medium resulted in formation of about three times more embryos as compared with controls. At higher concentrations, AgNO$_3$ reduced the numbers of visible embryos. The percentage of calli that formed embryos did not change appreciably over the range of concentrations of AgNO$_3$ tested. AVG at concentrations up to 10 µM had a minimal promotive effect on embryogenesis (data not presented).

**Discussion**

Somatic embryogenesis from root tissue of spinach requires both the formation of embryogenic callus from root explants and subsequent embryogenesis from the callus. These two processes have different growth regulator requirements. An exogenous supply of GA$_3$ in the presence of NAA promotes the first process, whereas the latter process does not require the exogenous supply of growth regulators (Komai et al. 1996a). In the present investigation, the addition of ethephon to the CI medium enhanced development of embryogenic callus. By contrast, addition of AgNO$_3$ or AVG reduced the rate of formation of embryogenic callus without reducing the growth rate of callus. Silver nitrate and AVG at 10 µM and 1 µM, respectively, completely inhibited...
formation of embryogenic callus from explants of spinach roots. These concentrations are similar to those at which ethylene inhibitors are effective in other plant tissue culture systems (Goh et al. 1997, Hatanaka et al. 1995, Kong and Yeung 1994, Lee et al. 1997, Roustan et al. 1990, Songstad et al. 1991, Vain et al. 1989). Our results suggest that ethylene is essential for development of embryogenic callus on explants of spinach roots and that application of ethylene promotes conditions that are favorable for initiation of somatic embryogenesis.

Enhancement of formation of embryogenic callus by ethephon was observed only when GA$_3$ was also supplied exogenously to cultures. Application of GA$_3$, plus an auxin to the CI medium effectively enhances the formation of embryogenic callus (Komai et al. 1996a, Xiao and Branchard 1993). Moreover, ethephon could not replace an exogenous supply of GA$_3$. With respect to the interactions between the effects of ethylene and those of gibberellins, there is some evidence that gibberellins mediate, to some extent, the effects of ethylene. Thus, for example, ethylene promotes growth of rice (Oryza sativa L.) seedlings by increasing the responsiveness of the internodal tissue to gibberellin (Hoffmann-Benning and Kende 1992). In young rice seedlings, ethylene stimulates elongation of leaves by increasing the responsiveness to GA$_3$, and the turnover of GA$_3$ (Furukawa et al. 1997). Therefore, it is likely that enhancement of the formation of embryogenic callus by exogenous ethylene is due to an increase of the responsiveness of cells to gibberellin. Moreover, spinach root tissues might be responsive to gibberellin only in the presence of ethylene.

Addition to the medium of ethephon during embryogenesis decreased the number of embryos formed on calli derived from root explants, and the addition of AgNO$_3$ at 10 to 100 $\mu$m increased the number of embryos. These observations suggest that ethylene might act to inhibit somatic embryogenesis in spinach. These findings agree with the results of many previous studies that indicate ethylene has an inhibitory effect on somatic embryogenesis. The limited promotive effect of 10 $\mu$m AVG on embryogenesis from spinach callus might have been due to incomplete inhibition of the biosynthesis of ethylene because of the low concentration of AVG employed or decomposition of this inhibitor.

This report provides a clear demonstration of the promotive and inhibitory actions of ethylene on in vitro somatic embryogenesis in explants of spinach roots. It also provides an improved protocol for in vitro regeneration of plants from spinach tissue that might be applicable to other species. However, it remains to be determined whether the development-dependent inhibition and stimulation that we observed involves production of ethylene, the sensitivity of the tissue to ethylene and/or interactions with the effects of other growth regulators.
