Shock formations are observed in granular avalanches when supercritical flow merges into a region of subcritical flow. In this paper we employ a shock-capturing numerical scheme for the one-dimensional Savage-Hutter theory of granular flow to describe this phenomenon. A Lagrangian moving mesh scheme applied to the non-conservative form of the equations reproduces smooth solutions of these free boundary problems very well, but fails when shocks are formed. A non-oscillatory central difference (NOC) scheme with TVD limiter or WENO cell reconstruction for the conservative equations is therefore introduced. For the avalanche free boundary problems it must be combined with a front-tracking method, developed here, to properly describe the margin evolution. It is found that this NOC scheme combined with the front-tracking module reproduces both the shock wave and the smooth solution accurately. A piecewise quadratic WENO reconstruction improves the smoothness of the solution near local extrema. The schemes are checked against exact solutions for (1) an upward moving shock wave, (2) the motion of a parabolic cap down an inclined plane and (3) the motion of a parabolic cap down a curved slope ending in a flat run-out region, where a shock is formed as the avalanche comes to a halt.

Key Words: Granular avalanche, shock-capturing, non-oscillatory central scheme, free moving boundary, front-tracking.

AMS Subject Classification code: 65M06, 35L67, 35R35, 86A60.

1. INTRODUCTION

Snow avalanches, landslides, rock falls and debris flows are extremely dangerous and destructive natural phenomena of which the occurrence has increased during the past few decades. Their human impact has become so significant that the United Nations declared 1990–2000 International Decade for Natural Disasters Reduction (IDNDR). Research on the protection of habitants from floods, debris flows and
avalanches is under way worldwide, and many institutions focus on the numerical prediction of such flows under ideal as well as realistic conditions.

One of the models that has become popular in recent years is the Savage-Hutter (SH) avalanche theory for granular materials [33, 34]. In the past decade numerical techniques were developed to solve the SH-governing differential equations for typical moving boundary value problems [33, 34, 13, 9, 10, 19, 16, 14, 8, 41, 6, 7]. These techniques are based on a Lagrangian moving mesh finite-difference scheme in which the granular material is divided into quadrilateral cells (2D) or triangular prisms with flat tops (3D). Exact similarity solutions of the SH-equations were constructed in spatially one-dimensional chute flows [33, 35, 31] and for two-dimensional unconfined flows [15, 12]. In the case of chute flows it was shown that the solutions obtained by the Lagrangian integration procedure approximate the exact parabolic similarity solution very accurately, and these theoretical and numerical results are in good agreement with experimental avalanche data. Similar agreement between theoretical, numerical and experimental data was also obtained for the two-dimensional flow configurations (cf. above references). In these Lagrangian schemes explicit artificial numerical diffusion was incorporated to maintain stability. In doing so the quality of resolution deteriorates. In fact, the adequacy of these numerical solutions can be challenged because of uncontrolled spreading due to this diffusion. It was also observed that the Lagrangian schemes loose their stability (or else unjustified artificial diffusion must be applied) whenever internal shocks are formed. This appears to occur whenever the avalanche moves from an extending to a contracting flow configuration. These shocks are travelling waves which form bumps with steep gradients on the free surface, which is thicker on the down slope side. It is therefore natural to develop conservative high-resolution shock-capturing numerical techniques that are able to resolve the steep surface gradients and identify the shocks often observed in experiments but not captured by the Lagrangian finite difference scheme.

The development of high-resolution shock-capturing schemes has a long history which we cannot even sketch here (see e.g. the classical references [3, 40, 11, 42] or the recent textbooks [25, 4, 20, 39]. The most common approach is to first develop a one-dimensional TVD (total-variation-diminishing) upwind scheme for a scalar conservation law and then apply it to systems using one-dimensional characteristic decompositions or approximate Riemann solvers. Upwind schemes have been used very successfully for gas dynamical calculations, where the Riemann problem can be solved exactly and many approximate Riemann solvers are available. For more complicated systems like the granular flow model considered here characteristic decompositions are often not available, and the Riemann problem cannot be solved analytically. Therefore we have chosen an alternative approach to high-resolution shock-capturing, namely the recent non-oscillatory central (NOC) schemes first introduced by Nessyahu and Tadmor [30]. While upwind schemes are higher order extensions of the classical Godunov scheme, central schemes build upon the (also classical) Lax-Friedrichs scheme [23]. This scheme avoids characteristic decompositions and Riemann solvers by the use of a staggered grid. When used together with piecewise constant spatial reconstructions, the Lax-Friedrichs scheme is more diffusive than Godunov’s scheme. However, when one combines the scheme with TVD-type piecewise linear reconstructions, it becomes competitive with the up-
wind schemes. Recently, central schemes have been extended in many directions, see e.g., [1, 2, 18, 27] for multidimensional extensions, [32] for an adaptive staggered scheme, [28, 26] for third- and higher-order schemes and [22, 21] for central schemes on non-staggered grids, which are precisely at the borderline of central and upwind schemes.

Here we adapt the second order NOC scheme of Nessyahu and Tadmor to include an earth pressure coefficient which has a jump discontinuity as the flow travels from an expanding into a contracting region, and to treat the source term which is due to the spatially varying topography and the gravitational force. The resulting scheme works well both in smooth regions and at shocks, which are captured within two mesh cells and without any oscillations.

Besides the formation of shock fronts in the interior, avalanches may also have a vacuum front at their margins. Similarly as for the equations of gas dynamics, the hyperbolic system degenerates at the vacuum state. Many shock capturing upwind schemes produce negative heights at these points and subsequently break down or become completely unstable. While our NOC scheme is remarkably stable at the margins, it does not capture the vacuum front as well as the Lagrangian moving mesh scheme. To overcome this imperfection, we augment the NOC scheme with an algorithm that tracks the vacuum front. The combined front-tracking non-oscillatory central scheme is accurate and robust both at shocks and at the margins of the granular avalanche.

The ensuing analysis commences in §2 with the presentation of the governing SH-equations in conservative and non-conservative form; then the jump conditions of mass and momentum at singular surfaces will be stated and the solution to a single shock wave (a hydraulic jump) will be presented; § 2 closes with the construction of exact similarity solutions of a parabolic heap moving down a rough incline. §3 introduces the numerical techniques; at first the Lagrangian integration technique is described; it is followed by the presentation of the non-oscillatory central (NOC) scheme. In §4 we augment the NOC scheme (which uses a fixed Eulerian grid) with a Lagrangian type front-tracking method in the marginal cells. §5 elaborates on numerical results. The travelling shock wave cannot be handled by the Lagrangian method, but the NOC scheme can do so with very little diffusion across the shock. On the other hand, the parabolic similarity solution is well produced by the Lagrangian integration technique, but much less accurately by the NOC schemes unless the Lagrangian front-tracking is introduced for the marginal cells. It is also shown that the NOC scheme with piecewise linear spatial reconstructions applying standard TVD type slope limiters exhibits some oscillations near smooth local maxima. We remove these oscillations by incorporating a piecewise quadratic WENO (weighted essentially non-oscillatory) reconstruction into our scheme. Our final numerical experiment combines all the difficulties treated in the paper: an avalanche with a vacuum front at the margins expands as it flows downhill and contracts as it hits the flat runout (so the earth pressure coefficient changes discontinuously at the transition point). As the avalanche comes to a halt at the bottom, a shock wave develops and propagates upslope. Our NOC front tracking scheme handles this challenging flow very satisfactorily. §6 presents conclusions and gives an outlook to further work.
2. GOVERNING EQUATIONS

A detailed derivation of the Savage-Hutter theory has been given in [33, 34]. Here we confine ourselves to a brief description. Although cohesionless granular materials exhibit dilatancy effects numerous experiments have confirmed that during rapid dense flow it is reasonable to assume that the avalanche is incompressible with constant uniform density $\rho_0$. During flow the body behaves as a Mohr-Coulomb plastic material at yield. As the avalanche slides over the rigid basal topography a Coulomb dry friction force resists the motion. The basal shear stress is therefore equal to the normal basal pressure multiplied by a coefficient of friction $\tan \delta$, where $\delta$ is termed the basal friction angle [19]. Scaling analysis isolates the physically significant terms in the governing equations and identifies those terms that can be neglected. Plane flow configurations are our focus in this paper, so depth integration reduces the theory to one spatial dimension. The leading order, dimensionless, depth integrated equations for the local thickness of the avalanche $h$ and the momentum $hu$ (u is the downslope velocity) reduce to

$$\frac{\partial h}{\partial t} + \frac{\partial}{\partial x}(hu) = 0, \quad (1)$$

$$\frac{\partial (hu)}{\partial t} + \frac{\partial}{\partial x}(hu^2 + \beta x h^2/2) = hs_x \quad (2)$$

with net driving force

$$s_x = \sin \zeta - \text{sgn}(u) \tan \delta (\cos \zeta + \lambda \kappa u^2) - \varepsilon \cos \zeta \frac{\partial z^b}{\partial x}, \quad (3)$$

where $x$ is the arc length measured along the avalanche track, $z^b$ denotes the height of the basal topography relative to the track (usually $z^b = 0$ in one spatial dimension) and $\zeta$ and $\lambda \kappa$ are the local slope inclination angle and curvature of the track, respectively. The term $\text{sgn}(u)$ selects the orientation of the dry Coulomb drag friction, and $\varepsilon \ll 1$ is the aspect ratio of a typical thickness and length of the avalanche. Note that equations (1) and (2) are written in conservative form [8], while in the original SH theory the smoothness assumption allows the momentum balance equation to transform to an evolution equation for the velocity, viz.,

$$\frac{du}{dt} = s_x - \beta_x \frac{\partial h}{\partial x} - \frac{1}{2} h \frac{\partial \beta_x}{\partial x}. \quad (4)$$

The factor $\beta_x$ is defined as $\beta_x = \varepsilon \cos \zeta K_x$ and the earth pressure coefficient $K_x$ is given by the ad hoc assumption

$$K_x = \begin{cases} K_{x,\text{act}} & \text{for } \frac{\partial u}{\partial x} > 0, \\ K_{x,\text{pass}} & \text{for } \frac{\partial u}{\partial x} < 0, \end{cases} \quad (5)$$

with

$$K_{x,\text{act/pass}} = 2 \left( \frac{1}{1 + \sqrt{1 - \cos^2 \phi / \cos^2 \delta}} \right)^2 \sec^2 \phi - 1, \quad (6)$$

and $\phi$ is the internal friction angle of the granular material. Note that the values of the earth pressure coefficient $K_x$ are based on the postulation of a Mohr-Coulomb
plastic behaviour for the cohesionless yield on the basal sliding surface, see Savage & Hutter [33, 34] for details. In this theory the earth pressure coefficient $K_x$ is assumed to be function of the velocity gradient, i.e. $K_x = K_x(\partial u/\partial x)$.

The governing equations look like the shallow-water equations, but because of the jump in the earth pressure coefficients $K_{x_{\text{act/pass}}}$, the source term $s_x$ and the free boundary at the front and rear margins, it becomes much more complicated to develop an appropriate numerical scheme to describe the flow. The original Lagrange finite-difference scheme [33] is implemented for the equation system (1) and (4) in Lagrangian form, with primitive variables $h$ and $u$. The shock capturing scheme developed here is applied to the system in conservative form (1) and (2), where the conserved quantities are the avalanche thickness $h$ and the depth integrated momentum $m = hu$.

In vector notation, equations (1) and (2) take the form

$$w_t + f_x = s, \tag{7}$$

where

$$w = \left( \begin{array}{c} h \\ m \end{array} \right), \quad f = \left( \begin{array}{c} m \\ m^2/h + \frac{1}{2}\beta_x h^2/2 \end{array} \right) \quad \text{and} \quad s = \left( \begin{array}{c} 0 \\ h s_x \end{array} \right). \tag{8}$$

This form is more convenient for mathematical analysis than (1) and (2).

### 2.1. Jump Condition and Travelling wave

The Savage-Hutter theory can be used to model the upslope propagating travelling shock wave observed in experiments [5, 7] by introducing the jump conditions (see Fig. 1) of the balance equations (1) and (2) for mass and momentum

$$[h(u - V_n)] = 0, \tag{9}$$

$$[hu(u - V_n) + \frac{1}{2}\beta_x h^2] = 0, \tag{10}$$

where $V_n$ is the normal speed of the singular surface. Let us suppose that $[\beta_x] = 0$ (for example, this is always satisfied if $\phi = \delta$, i.e., $K_{x_{\text{act}}} = K_{x_{\text{pass}}}$). Substituting (9) into (10) (i.e. eliminating $V_n$) yields the following relation between the depth ratio, $H := h^-/h^+$, and the velocity difference

$$(u^+ - u^-)^2 = \beta_x h^- \frac{H + 1}{2} \left( \frac{H - 1}{H} \right)^2. \tag{11}$$

For an upslope travelling shock wave with travelling wave speed $V_n$ and corresponding depth ratio $H$, the factor $\beta_x$ is a function of material and topographic parameters, $\phi$, $\delta$ and $\zeta$, which are given by the selected material and topography. Provided that the depths before and after the shock, $h^+$ and $h^-$, are known (they can be determined by experiment) and the downslope velocity is also given (it is normally equal to zero), then the upslope velocity can be determined by using (11)

$$u^+ = u^- \pm \frac{H - 1}{H} \left( \beta_x h^- \frac{H + 1}{2} \right)^{1/2}. \tag{12}$$
The plane travelling shock wave can be interpreted as a jump in thickness and velocity separating the body of the avalanche into two parts on a plane with inclined angle $\zeta$. $h^+$ and $h^-$ are the thicknesses of both sides and $u^+$ and $u^-$ are the velocities, respectively, whereas this jump travels with velocity $V_n$ up-slopes.

Note that the term under the square root is positive for all positive $H$. If $H = 1$ then $u^+ = u^-$, which indicates that no shock wave (discontinuity) takes place. Thus, velocity jumps and depth jumps occur together.

By inspection of the mass balance equation (9), the velocity of the shock is given by

$$V_n = \frac{H u^- - u^+}{H - 1} = u^- + \left[\beta_x h^- \frac{H + 1}{2H^2}\right]^{1/2}. \quad (13)$$

Note that as $h^+$ tends to $h = h^-$, then $u^+$ tends to $u = u^-$ and

$$V_n \rightarrow u \mp [\beta_x h]^{1/2}, \quad (14)$$

so we have recovered the characteristic speeds of the shallow water equations. Now we apply Lax’ shock inequalities [24] to single out the physically relevant branches of the shock curves: for the first family, with characteristic speed $u - \sqrt{\beta_x h}$, we require that

$$u^+ - [\beta_x h^+]^{1/2} > V_n = u^- - \left[\beta_x h^- \frac{H + 1}{2H^2}\right]^{1/2} > u^- - [\beta_x h^-]^{1/2},$$

which implies $H > 1$ (recall that the upslope state “+” lies to the left of the shock). Analogously, for the second family, with characteristic speed $u + \sqrt{\beta_x h}$, we obtain $H < 1$. For example, an upward jump ($h^+ < h^-$) can only be carried by a shock of the first family, and in this case $u^+ > u^- > V_n$, so particles which cross the shock are condensed and slow down.

### 2.2. Similarity Solution

Consider the motion of a finite mass of granular material along a flat plane, i.e. $\zeta$ is constant and $\lambda \kappa = 0$ in (3). In [33] one particular similarity solution to a moving boundary problem of finite mass was derived; this solution is now generalised (see [36]). To this end we introduce a moving coordinate system with velocity

$$u_0(t) = u_0(0) + \int_0^t (\sin \zeta - \tan \delta \cos \zeta) \, dt \quad (15)$$
on an plane with inclination angle $\zeta$. This velocity is due to the net driving force $s_x$ in (3), where we assume that the velocity is positive for positive times, i.e. $\text{sgn}(u) = 1$. The relative velocity $\tilde{u}$ in the moving coordinate system is then given by

$$\tilde{u} = u - u_0(t). \quad (16)$$

A symmetric bulk is considered and the origin of the moving coordinate system is selected to lie at the centre where the surface gradient, $\partial h/\partial x$, is zero. To keep the symmetric depth profile during the motion the relative velocity is further assumed to be skew-symmetric, $\tilde{u}(\xi, t) = -\tilde{u}(-\xi, t)$, where

$$\xi = x - \int_0^t u_0(t') \, dt' \quad (17)$$

indicates the distance from the origin in the moving coordinates. Provided that $g(t)$ is the distance from the coordinate origin to the margin at time $t$, the physical domain occupied by the granular mass can be mapped from $[-g(t), g(t)]$ to the fixed domain $[-1, 1]$ by

$$\eta = \frac{1}{g(t)} \left\{ x - \int_0^t u_0(t') \, dt' \right\}, \quad \text{where} \quad \eta \in [-1, 1]. \quad (18)$$

With this coordinate mapping, $(x, t) \to (\eta, \tau)$, the model equations (1) and (2) reduce to

$$\frac{\partial h}{\partial t} - g' \frac{\partial h}{\partial \eta} + \frac{1}{g} \frac{\partial}{\partial \eta} (h \tilde{u}) = 0, \quad (19)$$

$$\frac{\partial \tilde{u}}{\partial t} - g' \frac{\partial \tilde{u}}{\partial \eta} + \frac{1}{g} \left( \tilde{u} \frac{\partial \tilde{u}}{\partial \eta} + \beta_x \frac{\partial h}{\partial \eta} \right) = 0, \quad (20)$$

where the $\tau$ is again replaced by $t$ and we have used $g' = dg/dt = -u_0/\eta$.

Now we assume that $\tilde{u}(\eta, t)$ varies linearly in $\eta$. Since the margins move with relative speeds $\pm g'(t)$, this yields $\tilde{u}(\eta, t) = \eta g'(t)$. Now the evolution equations (19) and (20) reduce to

$$\frac{\partial h}{\partial t} + \frac{g'}{g} h = 0, \quad (21)$$

$$\eta g'' + \frac{\beta_x}{g} \frac{\partial h}{\partial \eta} = 0, \quad (22)$$

where $g'' = d^2g/dt^2$. Integrating (22) subject to the boundary condition either $h(\eta = 1) = 0$ or $h(\eta = -1) = 0$, it follows that the thickness is described by

$$h(\eta, t) = \frac{g(t)g''(t)}{2\beta_x} (1 - \eta^2). \quad (23)$$

This implies that the avalanche body keeps a parabolic thickness distribution during the motion. With the thickness distribution (23) one can easily obtain the total mass $M$ to be

$$M = \int_{\xi_f}^{\xi_i} h(\xi, t) \, d\xi = \int_{-1}^{1} h(\eta, t) g(t) \, d\eta = \frac{2}{3} \frac{g''g^2}{\beta_x}. \quad (24)$$
Since mass is conserved,
\[ 0 = \frac{d}{dt} M = \frac{2\beta}{3\beta_x} (2g'g'' + gg'''). \] (25)

This relation can also be derived directly from the mass balance equation (21).

Changing the independent variable \( t \) to \( g(t) \) and letting \( p(t) = g'(t) \), equation (24) can be written as
\[ \frac{dp}{dg} = \frac{K}{g^2}, \] (26)
where \( 3\beta_x M = 2K \). The similarity solution is then obtained by solving (26) with initial condition, \( g(0) = g_0 \) and \( p(0) = p_0 \)
\[ p^2(t) = 2K \left( \frac{1}{g_0} - \frac{1}{g(t)} \right) + p_0^2. \] (27)

With the definition \( \alpha_g = \frac{2K}{g_0}, \beta_g = p_0^2 \) and \( G = (\alpha_g + \beta_g) g \) it follows that
\[ \frac{\sqrt{G} G'}{\sqrt{G} - 2K} = (\alpha_g + \beta_g)^{3/2}. \] (28)

We now use the relation
\[ \frac{d}{dG} \left[ \sqrt{G} \sqrt{G - 2K} + 2K \ln(\sqrt{G} + \sqrt{G - 2K}) \right] = \frac{\sqrt{G}}{\sqrt{G} - 2K} \]
and integrate equation (28) to yield
\[ \sqrt{G} \sqrt{G - 2K} + 2K \ln(\sqrt{G} + \sqrt{G - 2K}) \]
\[ - \left[ \sqrt{G} \sqrt{G - 2K} + 2K \ln(\sqrt{G} + \sqrt{G - 2K}) \right]_{t=0} = (\alpha_g + \beta_g)^{3/2} t. \] (29)

With \( g_0 = 1, p_0 = 0 \) we obtain the Savage-Hutter solution [33]
\[ \sqrt{g} \sqrt{g - 1} + \ln \left( \sqrt{g} + \sqrt{g - 1} \right) = \sqrt{2K} t, \] (30)
for which \( g(t) > 1 \). Both (29) and (30) are implicit evolution equations for \( g(t) \). Once \( g(t) \) is deduced, with the presumption \( \bar{u}(\eta, t) = \eta g'(t) \), the complete solution is then given by (23) and (27),
\[ \bar{u}(\eta, t) = \eta \left\{ 2K \left( \frac{1}{g_0} - \frac{1}{g(t)} \right) + p_0^2 \right\}^{1/2}, \quad h(\eta, t) = \frac{3M}{4 g(t)(1 - \eta^2)}, \] (31)
where \( \eta \) is defined in (18). In the present similarity solution it is presumed that \( u/|u| = 1 \), which means that \( u > 0 \) for all \( t \geq 0 \). From (16) and the presumption \( \bar{u}(\eta, t) = \eta g'(t) \) it follows that
\[ u(t) = u_0(t) + \bar{u}(t) > 0 \quad \Rightarrow \quad g'(t) < u_0(t), \quad \text{for all } \quad t \geq 0. \] (32)

It is very important to verify that the velocity is consistent with condition (32) to keep the parabolic similarity solution valid. The generalisation (29) of (30)
was needed to have exact solutions with non-vanishing initial velocities (for further details see [36]).

3. NUMERICAL SCHEME

The numerical schemes employed in this paper are designed to explicitly solve the system of equations in 1D and we here introduce a Lagrangian algorithm and an Eulerian shock-capturing NOC (Non-Oscillatory Central) scheme.

In the Lagrangian technique [33, 34] the avalanche body is divided into several cells. The purpose is to find the velocity of the cell boundaries in order to determine the cell boundary locations for each time step; so it is a moving-grid method, whereas, the NOC scheme is built on a stationary uniform grid and gives a high resolution of the shock solutions without any spurious oscillations near a discontinuity.

In the Lagrangian method the value of the depth \( h^n_j \) is defined as the volume average within the \( j \)th cell for time \( t^n \), which is bounded by \( b_{j-1}(t) \) and \( b_j(t) \), and the boundary \( b_j(t) \) moves with the velocity \( u_j \). Whilst, in the NOC scheme the value of the discretised variable \( U^n_j \), \( U = h, m \) is defined on the mesh as the volume average within the \( j \)th mesh cell centred at position \( x_j \) for time \( t^n \), where the \( j \)th cell is bounded by \( x_{j+1/2} \) and \( x_{j-1/2} \).

3.1. Lagrangian method

In the Lagrangian method [33, 34] the avalanche body is divided into \( N \) material cells, where \( x = b_{j-1}(t) \) and \( x = b_j(t) \) denote the boundaries of the cell \( j \) at time \( t \), see Fig. 2. These boundaries move with the avalanche velocity, i.e.

\[
\frac{d}{dt} b_j(t) = u_j(t) = u(b_j(t), t).
\]

Integrating the mass balance equation (1) over the cell yields

\[
\int_{b_{j-1}}^{b_j} \left\{ \frac{\partial h}{\partial t} + \frac{\partial}{\partial x} (hu) \right\} \, dx = \frac{d}{dt} \int_{b_{j-1}}^{b_j} h \, dx = 0 \quad \Rightarrow \quad \frac{d}{dt} V_{\text{cell}_j} = 0, \tag{33}
\]

and implies that the volume (mass) of the cell is conserved during the motion. Because of this, the mean height of the \( j \)th cell can be determined by

\[
h^n_j = \frac{V_{\text{cell}_j}}{b^n_j - b^n_{j-1}}. \tag{34}
\]

The computations proceed as follows. It is assumed that \( b^n_j, h^n_j \) and \( u^{n+1/2}_j \) are given as initial values and the new location of the cell boundary \( b^{n+1}_j \) after an elapsed time \( \Delta t \) is given by

\[
b^{n+1}_j = b^n_j + \Delta t \, u^{n+1/2}_j. \tag{35}
\]
The avalanche body is divided into $N$ elements with average depth $h_j$, where $c_j$ is the centre of the $j^{th}$ element.

Note that here the velocity $u_j$ indicates the boundary velocity of $b_j$. The momentum balance (4) allows the velocity of the cell boundary at time $t^{n+1/2}$ to be determined,

$$u_j^{n+1/2} = u_j^{n-1/2} + \Delta t \left\{ s_j^n - \varepsilon \cos \zeta_j (K_x)_j^n \left( \frac{\partial h}{\partial x} \right)_j^n - \frac{h_j^n}{2} \left( \frac{\partial (\cos \zeta K_x)}{\partial x} \right)_j^n \right\}. \tag{36}$$

The net driving acceleration $s_j^n$ as given by (3) is

$$s_j^n = \sin \zeta_j - \text{sgn} \left( u_j^{n-1/2} \right) \tan \left\{ \cos \zeta_j + \lambda \kappa_j \left( u_j^{n-1/2} \right)^2 \right\} - \varepsilon \cos \zeta_j \left( \frac{\partial z^b}{\partial x} \right)_j^n, \tag{37}$$

where $\zeta_j$ represents the local inclination angle, $\kappa_j$ is the local curvature, and $z^b$ denotes the local basal topography. Note that the last term at the right-hand side of (36) contains the gradient of the earth pressure coefficient, which is neglected in the numerical scheme of Savage and Hutter [33, 34].

The earth pressure coefficient $K_x$ is determined by the ad hoc definition

$$(K_x)_j^n = \begin{cases} K_{x\text{act}}, & \text{for } u_{j+1}^{n-1/2} \geq u_j^{n-1/2}, \\ K_{x\text{pass}}, & \text{for } u_{j+1}^{n-1/2} < u_j^{n-1/2} \end{cases} \tag{38}$$

in [33, 34]. The surface (depth) gradients in (36) are determined by the depths of the adjacent elements

$$\left( \frac{\partial h}{\partial x} \right)_j^n = \frac{h_j^n + 1 - h_j^n}{c_{j+1}^n - c_j^n} = \frac{2(h_j^n - h_{j-1}^n)}{b_{j+1}^n - b_{j-1}^n}. \tag{39}$$

where $c_j^n$ represents the centre of the $j^{th}$ cell, $c_j^n = (b_j^n + b_{j-1}^n)/2$, at time $t^n$, see Fig. 2. The height at the cell boundary, $h_{j+1/2}$, is given by their mean values in adjacent cells, $h_{j+1/2} = \frac{1}{2}(h_j + h_{j+1})$, and the gradient of the earth pressure coefficient is

$$\left( \frac{\partial (\cos \zeta K_x)}{\partial x} \right)_j^n = \frac{\cos \zeta_{j+1} (K_x)_j^{n+1} - \cos \zeta_j (K_x)_j^n}{c_{j+1}^n - c_j^n}. \tag{40}$$

However, while this method is excellent for classical smooth solutions, it loses numerical stability if shocks develop. Shocks are initiated when the avalanche velocity is faster than its characteristic speed and the avalanche front reaches the
base of the slope or a solid wall. Many detailed investigations about granular shocks were made by Gray and Hutter [5], in which the shock waves are concerned to be an important property in the granular flows. To avoid the numerical instability caused by the shocks, an artificial viscosity term $\mu \frac{\partial^2 u}{\partial x^2}$ is introduced and added to the right hand side of (37) for numerical stability, e.g. [33, 34] and [14], where the artificial viscosity $\mu$ was found to have values between 0.01 and 0.03.

### 3.2. NOC Scheme

The Non-Oscillatory Central Differencing (NOC) scheme of Nessyuhu and Tadmor [30] is a second order accurate extension of the classical Lax-Friedrichs scheme [23]. Let us briefly review the NOC scheme:

We consider the Savage-Hutter equations in the conservative form (7), (8) with $w = (h, m)^T$ as basic variables. Let $\mathbf{w}_j^n$ denote the cell average over interval $[x_{j-1/2}, x_{j+1/2}]$ at time $t^n$, and let

$$\mathbf{w}(x, t^n) = \mathbf{w}_j^n + \frac{x - x_j}{\Delta x} \mathbf{w}_j^n$$

be a piecewise linear reconstruction over the cell, where $\mathbf{w}_j^n$ denotes the cell mean derivative determined by a TVD-limiter [25] or a central WENO cell reconstruction [26]. The main conceptional difference between the NOC schemes and standard upwind finite difference schemes is the use of a staggered grid. At time $t^{n+1} = t^n + \Delta t$, the cell averages $\mathbf{w}_j^{n+1}$ are evaluated over the intervals $[x_j, x_{j+1}]$, see Figure 3. As a consequence, the boundaries of the cells at the new time level are the centers of the cells at the old time level, namely the points $x_j$ and $x_{j+1}$. At these points, the piecewise polynomial reconstruction (41) of the cell averages at the old time level $t^n$ is smooth, and it remains so for $t < t^{n+1}$ under an appropriate restriction of the timestep (see (49) below). Therefore, the flux across the boundaries of the cells at the new time level may be evaluated by Taylor extrapolations using the differential equation and standard quadrature rules. Here we use the midpoint rule in time to achieve second order accuracy. The resulting update takes the form

$$\mathbf{w}_{j+1/2}^{n+1} = \frac{1}{2} \left( \mathbf{w}_{j+1/4}^n + \mathbf{w}_{j+3/4}^n \right) - \frac{\Delta t}{\Delta x} \left( f_{j+1/2}^{n+1/2} - f_j^{n+1/2} \right) + \frac{\Delta t}{2} \left( s_{j+1/4}^{n+1/2} + s_{j+3/4}^{n+1/2} \right),$$

where

$$a_j = \frac{j}{n+1}$$
as illustrated in Fig. 3b. The values of $\vec{w}_{j+1/4}^n$ and $\vec{w}_{j+3/4}^n$ are determined by the reconstruction (41) over the $j^{th}$ and $(j + 1)^{th}$ cell, i.e.

$$\vec{w}_{j+1/4}^n = \vec{w}_j^n + \frac{1}{4}\vec{w}_j', \quad \vec{w}_{j+3/4}^n = \vec{w}_{j+1}^n - \frac{1}{4}\vec{w}_{j+1}' .$$  \hspace{1cm} (43)

The transport flux $f$ at the quadrature points $(x_j, t^{n+1/2})$ and $(x_{j+1}, t^{n+1/2})$ is approximated by Taylor extrapolation in time,

$$f_j^{n+1/2} = f \left( \vec{w}_{j+1/2}^{n+1/2} \right), \quad \vec{w}_{j+1/2}^{n+1/2} = \vec{w}_j^n + \frac{\Delta t}{2} (\partial \vec{w}/\partial t)_j^n, \hspace{1cm} (44)$$

and similarly, the source terms $s$ at the quadrature points $(x_{j+1/2}, t^{n+1/2})$ and $(x_{j+3/4}, t^{n+1/2})$ are approximated by space-time Taylor extrapolation

$$s_{j+1/2}^{n+1/2} = s \left( \vec{w}_{j+1/4}^{n+1/2} \right), \quad \vec{w}_{j+1/4}^{n+1/2} = \vec{w}_j^n + \frac{\Delta t}{2} (\partial \vec{w}/\partial t)_j^n + \frac{1}{4}\vec{w}_j', \hspace{1cm} (45)$$

The temporal derivative $(\partial \vec{w}/\partial t)_j^n$ in (44) and (45) is determined by using (7),

$$(\partial \vec{w}/\partial t)_j^n = - (\partial \vec{f}/\partial x)_j^n + s_j^n = -A_j \vec{w}_j'/\Delta x + s_j^n , \hspace{1cm} (46)$$

where

$$(\partial \vec{f}/\partial x)_j^n = (A)_j^n (\partial \vec{w}/\partial x)_j^n, \quad A = \partial \vec{f}/\partial \vec{w} = \begin{pmatrix} 0 & 1 \\ -\frac{m^2}{\Delta x} + \beta_j h & 2m_j/\Delta x \end{pmatrix} \hspace{1cm} (47)$$

and $A$ is the Jacobian of $\vec{f}$. Alternatively, one may also use the Jacobian-free approach of Nessyahu and Tadmor [30] and set

$$(\partial \vec{f}/\partial x)_j^n = \vec{f}_j'/\Delta x,$$

where the cell mean derivative $\vec{f}'$ of the flux is again determined by a TVD-limiter. Let $a_{max}^\Delta$ be the maximum wave speed,

$$a_{max}^\Delta = \max_{all \ j} \left( |u_j| + \sqrt{\beta_j h_j} \right), \quad u_j = m_j/h_j \quad \text{for} \quad h_j \neq 0 . \hspace{1cm} (48)$$

The CFL condition

$$\frac{\Delta t}{\Delta x} |a_{max}^\Delta| < \frac{1}{2}, \quad \text{for all} \quad j \hspace{1cm} (49)$$

is needed to guarantee that the solution remains smooth at the space-time quadrature points, so that the Taylor expansions (44) and (45) are justified.

Note that the NOC scheme (41) – (49) completely avoids the expensive Riemann solvers used in standard upwind schemes on non-staggered grids. The resulting staggered schemes are easy to code, computationally efficient and can be applied to general systems of conservation laws, where the solution of the Riemann problem (i.e. the initial value problem with piecewise constant data) may complicated or even impossible.
4. FRONT-TRACKING METHOD

In many applications, the region covered by the granular material has a finite extension and is limited by a free boundary which moves with the flow velocity. Outside this region, there is vacuum, so the avalanche height $h$ and momentum $m$ are zero, and the velocity $u = m/h$ is not well-defined. The Lagrangian method handles this situation automatically, since the computational domain moves with the material flow. The NOC scheme discretizes the differential equations on a stationary uniform mesh. Note that in general the margin points $x_{n F}^n$ (the front margin) and $x_{n T}^n$ (the tail margin) lie between grid points, so that it is impossible to point out the margin locations without extra treatment. Furthermore, it is not straightforward to determine the proper cell reconstructions over the margin cells.

Fig. 4 illustrates an example of depth reconstructions over the front margin cell determined by various TVD limiters. Here and in the following we suppose that at time $t_n$, the front margin lies in the $f$th cell, $x_{f-1/2}^n \leq x_{n F}^n < x_{f+1/2}^n$, and the tail margin in the $t$th cell, $x_{t-1/2}^n \leq x_{n T}^n < x_{t+1/2}^n$.

![Fig. 4. Example of the depth reconstruction (solid line) determined by different TVD limiters, where the circles denote the cell average. The front margin lies in the $f$th cell. In the Eulerian scheme one cannot determine where the margin lies. Outside the margin there is no material, so that the average depths of the cells $f+i$, $i \geq 1$ are equal to zero. Different limiters lead to different outflows from the avalanche body.](image)

Since our quadrature rule for the fluxes (44), (46), (47) uses a Taylor expansion of the solution, different limiters will lead to different values of the integrals of the fluxes across $x_f \times [t_n, t_{n+1}]$ and $x_t \times [t_n, t_{n+1}]$. To complicate the situation even further, part of these boundaries may lie in the vacuum region. Note that the fluxes across these boundaries determine the outflow from the avalanche body, so non-appropriate cell reconstructions over the margin cell may cause too much outflow from the avalanche body or even result in a negative depth around the margin, see Fig. 5a. Thus, the difficulty is not only to determine the correct numerical
flux at the grid point $x_f$, the wrong numerical flux may also cause vast stability problems. Adding a thin layer over the whole computational domain can circumvent the numerical stability problem, but it is then difficult to determine the locations of the margins, and the numerical flux out of the avalanche body would even become unexpectedly large, which results in large numerical diffusion, while there will be permanent outflow from the avalanche body. Therefore, a more refined treatment is needed for the evolution of the avalanche margins.

In [29], Munz developed a method to track vacuum fronts in gas dynamics. His approach is based on appropriate reconstructions of cell averages behind the front, and the solution of a vacuum Riemann problem which is used to track the margin locations at every time step. Here we develop an alternative front tracking method, which is based on a piecewise linear spatial reconstruction of the conservative variables up to the front and Taylor extrapolations in time. Contrary to [29] our approach is Riemann-solver free and therefore fits perfectly into the framework of central schemes.

The structure of our front-tracking algorithm is as follows: At the beginning of each timestep (at time $t_n$), the cell averages $\mathbf{w}_j^n$ of the conservative variables and the position of the margin points $x_{P_j}^n$ (front) and $x_{T_j}^n$ (tail) are given. In the first step, a piecewise linear reconstruction of the data is defined, the front (tail) velocity is determined and the front (tail) is propagated from time $t_n$ to $t_{n+1}$. In the second step, the conservative variables are updated via

$$
\mathbf{w}_{j-1/2}^{n+1} = \frac{1}{\Delta x} \int_{x_{j-1}}^{x_j} \mathbf{w}(x, t^n) \, dx - \frac{1}{\Delta x} \int_{t^n}^{t_{n+1}} \{f(x_j, t) - f(x_{j-1}, t)\} \, dt
+ \frac{1}{\Delta x} \int_{t^n}^{t_{n+1}} \int_{x_{j-1}}^{x_j} s(x, t) \, dx \, dt,
$$

Away from the front, the integrals are evaluated by the midpoint rule as in (42). Special care has to be taken in the two margin cells (the cells containing the front and the tail). Each of the integrals on the RHS of (50) may contain parts of the vacuum region. Therefore, we need to replace the midpoint rule by more delicate quadrature rules over the region covered by the granular material.

In order to guide the reader through the details of the algorithm, we would like to give an outline of the rest of this section. In Section 4.1, a particular piecewise linear reconstruction of the conservative variables near the front is derived. In Section 4.2, the front velocities are computed, and the fronts are propagated to the new time level. In Section 4.3, four cases are distinguished for the location of the front relative to the fixed underlying grid, and their geometry is discussed. In Sections 4.4, 4.5 and 4.6, the three integrals on the RHS of (50) are treated: the data, the fluxes and the source terms. In Section 4.7, a special space-time Taylor extrapolation of the conservative variables near the front is derived, which is needed to compute the solution at the space-time quadrature points of the three integrals. Section 4.8 summarizes the algorithm.

### 4.1. Reconstructing the conservative variables
Suppose as before that the front margin is contained in the \(f^{th}\) cell, and the rear margin in the \(t^{th}\) cell,

\[
x^n_{Ft} \in [x_{f-\frac{1}{2}}, x_{f+\frac{1}{2}}],
\]

\[
x^n_{Tl} \in [x_{t-\frac{1}{2}}, x_{t+\frac{1}{2}}].
\]

We require that the piecewise linear reconstruction \(\mathbf{w}(x, t_n)\) satisfies the following two criteria:

- first, it should vanish at the margin points, and
- second, it should preserve the cell averages.

These criteria uniquely determine the reconstruction in the margin cells. If we denote the cell averaged depths of the front margin and rear margin cells by \(h_f\) and \(h_t\), the depth reconstruction is defined by

\[
\tilde{h}_f(x) = \sigma_f^h(x - x_{Ft}); \quad \sigma_f^h = \frac{-2h_f \triangle x}{(x_{Ft} - x_{f-1/2})^2}, \quad \text{for } x \in [x_{f-1/2}, x_{Ft}], \tag{51}
\]

for the front margin cell and by

\[
\tilde{h}_t(x) = \sigma_t^h(x - x_{Tl}); \quad \sigma_t^h = \frac{2h_t \triangle x}{(x_{t+1/2} - x_{Tl})^2}, \quad \text{for } x \in [x_{Tl}, x_{t+1/2}], \tag{52}
\]

for the rear margin cell. Outside the margin the depth is equal to zero. The \(x_{Ft}\) and \(x_{f-1/2}\) represent the locations of the front and the internal boundary of the front margin cell, respectively (see Fig. 5). The \(x_{Tl}\) and \(x_{t+1/2}\) denote the locations of the rear and the internal boundary of the rear margin cell, respectively. The reconstruction of \(m = hu\), \(\tilde{m}(x)\), is defined analogously.

### 4.2. Propagating the front

Besides being very natural and simple, our definition of the reconstructions over the margin cells has the advantage of leading to uniquely defined, constant values

![FIG. 5.](image)

The reconstruction of the depth \(\tilde{h}_f(x)\) within the margin \(f^{th}\) cell. (a) Cell reconstructions based on TVD-limiters cannot determine the location of the margin point. Non-appropriate reconstructions over the margin cell may result in wrong values of the flux at the gridpoint \(x_f\), which may cause too much outflow from the avalanche body. (b) Our front tracking method uses the unique piecewise linear reconstruction \(\tilde{h}_f(x)\) over the margin cell which vanishes at the margin point \(x_{Ft}\) and preserves the cell average. Thus, a reasonable flux at \(x_f\) is expected.
of the velocities over the whole margin cells,

\[ u(x, t_n) = \hat{m}_{f/t}(x) = \frac{\sigma_{f/t}^n(x - x_{Ft/Tl})}{\sigma_{f/t}^n(x - x_{Ft/Tl})} = \frac{m_{f/t}}{h_{f/t}}. \]

It is therefore natural to define the margin velocities by these constant values,

\[ u_{Ft/Tl}^n = \frac{m_{f/t}}{h_{f/t}}. \] (53)

Alternatively, we may also approximate the margin velocity at time \( t_{n+1/2} \) in order to evolve the margin with second order accuracy. Using the evolution equation (4) for the velocity we define

\[ u_{Ft/Tl}^{n+1/2} = u_{Ft/Tl}^n + \frac{\Delta t}{2} \left( s_{f/t}^n - \beta_x \sigma_{f/t}^n \right). \] (54)

Here we have used the fact that \( h \) vanishes at the front. The location of the margin at the new time level is then given by

\[ x_{Ft/Tl}^{n+1} = x_{Ft/Tl}^n + \Delta t u_{Ft/Tl}, \] (55)

where either \( u_{Ft/Tl} = u_{Ft/Tl}^n \) or \( u_{Ft/Tl} = u_{Ft/Tl}^{n+1/2} \).

### 4.3. Intersecting the front and the grid

Once the new location of the margin is given, the new margin cell at the next time step is then determined. The CFL condition (49) guarantees that \( \left| u_{Ft/Tl}^n \Delta t \right| < \Delta x/2 \), so the margin point \( x_{Ft/Tl} \) can at most pass through gridpoint \( x_{f/t} \) during one time step. For example, with this condition the front can only lie in either one of the two adjacent cells of the margin \( f^{th} \) cell, which are the \((f - 1)^{th}\) and \((f + 1)^{th}\) cells, see Fig. 6. There are four possible cases for the motion of the front margin point:

- **case I**: \( x_{Ft}^n \leq x_f \), and \( x_{f-1} < x_{Ft}^{n+1} \leq x_f \),
- **case II**: \( x_{Ft}^n > x_f \), and \( x_f < x_{Ft}^{n+1} \leq x_{f+1} \),
- **case III**: \( x_{Ft}^n \leq x_f \), and \( x_f < x_{Ft}^{n+1} \leq x_{f+1/2} \),
- **case IV**: \( x_{Ft}^n > x_f \), and \( x_{f-1/2} < x_{Ft}^{n+1} \leq x_f \),

where \( x_{Ft}^n \) and \( x_{Ft}^{n+1} \) are the front locations at \( t^n \) and \( t^{n+1} \), respectively. In cases I and II, the front does not pass gridpoint \( x_f \), while in the cases III and IV it does, see Figure 6. In each case we have to determine the cell averages of the relevant cells \( \overline{w}_{f-1/2}^{n+1} \) and \( \overline{w}_{f+1/2}^{n+1} \) by integrating the governing equations over \([x_{f-1}, x_f] \times [t^n, t^{n+1}]\) and \([x_f, x_{f+1}] \times [t^n, t^{n+1}]\), respectively, i.e., we have to evaluate the three integrals on the RHS of (50). These integrals involve the data \( w \), the fluxes \( f \) and the source term \( s \). In the following, we derive quadrature rules which are exact for linear functions. The tail margin can be treated completely analogously.

#### 4.4. The integral of the data
FIG. 6. The four cases for the propagation of the front margin.

In cases I, III and IV replace by correct figures!!
First we integrate the linear reconstruction \( w(x, t^n) \) of the data at time \( t^n \) over the interval \([x_{f-1}, x_f]\). In cases I and III, this interval contains the front, while it does not in cases II and IV. We obtain

\[
\frac{1}{\Delta x} \int_{x_f}^{x_{f-1}} w(x, t^n) \, dx = \begin{cases} 
\frac{1}{2} w_f^{3/4} + w_f^n & \text{in cases I and III} \\
\frac{1}{2} (w_f^{3/4} + w_{f-1/4}^n) & \text{in cases II and IV}
\end{cases}
\]  

(56)

Here \( w_f^{-3/4} \) is given by (43), and \( w_f^{n-1/4} \) by (51). With a given front location \( x^n_{Ft} \) and \( w_f^n \) it is

\[
w_f^{-1/4} = 2 w_f^n \left\{ 1 - \left( \frac{x^n_{Ft} - x_f}{x^n_{Ft} - x_{f-1/2}} \right)^2 \right\}.
\]  

(57)

Next we consider the integral over the interval \([x_f, x_{f+1}]\). Using (51) once more we obtain

\[
\frac{1}{\Delta x} \int_{x_{f+1}}^{x_f} w(x, t^n) \, dx = \begin{cases} 
0 & \text{in cases I and III} \\
\frac{1}{2 \Delta t} \left( w_f^n \right)^2 (x^n_{Ft} - x_{f+1/2})^2 & \text{in cases II and IV}
\end{cases}
\]  

(58)

4.5. The integral of the fluxes

Due to the restriction of the timestep, the only grid-position which is possibly intersected by the front during the time-interval \([t^n, t^{n+1}]\) is \( x = x_f \). Therefore, the flux at \( x_{f-1} \) can be evaluated exactly as in the interior of the domain,

\[
\frac{1}{\Delta t} \int_{t^n}^{t^{n+1/2}} f(w(x_f - 1, t)) \, dt = f^{n+1/2}_f,
\]  

(59)

where \( f^{n+1/2} \) is given by (44). The flux at \( x_{f+1} \) vanishes, since this point lies in the vacuum region during the whole time interval. It remains to compute the flux at \( x_f \). In cases III and IV, where the front crosses \( x_f \), we use the midpoint-rule in time over that part of the interface which lies within the region covered by granular material. Let \( \bar{t} \) and \( \Delta t \) be the midpoint and the length of this time interval. If \( t^* \) is the time at which the front intersects \( x_f \), defined by

\[
x^n_{Ft} + (t^* - t_n)u^n_{Ft} = x_f,
\]  

(60)

then

\[
\bar{t} = \begin{cases} 
(t_{n+1} + t^*)/2 & \text{in case III} \\
(t_n + t^*)/2 & \text{in case IV}
\end{cases}
\]  

(61)

and

\[
\Delta t = \begin{cases} 
t_{n+1} - t^* & \text{in case III} \\
t^* - t_n & \text{in case IV}
\end{cases}
\]  

(62)

The midpoint rule for the flux now gives

\[
\frac{1}{\Delta t} \int_{t^n}^{t^{n+1/2}} f(w(x_f, t)) \, dt = \begin{cases} 
0 & \text{in case I} \\
f^{n+1/2}_f & \text{in case II} \\
\frac{\Delta t}{\Delta t} f_f & \text{in cases III and IV}
\end{cases}
\]  

(63)
Here \( f_j = f(w(x_f, \bar{t})) \). In Section 4.7 below we will extrapolate the solution \( w \) to the quadrature point \( (x_f, \bar{t}) \).

### 4.6. The integral of the source term

The source term \( s \) has to be integrated over the quadrilateral regions shown in Figure 6. Let us call these areas of integration \( \Omega \). In the following lemma, we give a quadrature rule which is exact for linear functions vanishing at the front.

**Lemma 4.1.** Let \( a, b, \tau \geq 0 \) and

\[
\Omega := \{(x, t) : \hat{t} \leq t \leq \hat{t} + \tau, \hat{x} \leq x \leq \hat{x} + a + (b - a)(t - \hat{t})/\tau\}.
\]

Let \( s \) be a linear function over \( \Omega \) which vanishes at the boundary \( x = \hat{x} + a + (b - a)(t - \hat{t})/\tau \). Then

\[
\int \int_{\Omega} s(x, t) dxdt = -\frac{\tau}{6} (a^2 + ab + b^2) =: \omega s(\hat{x}, \hat{t} + \tau/2).
\]

**Proof:** W.l.o.g. let \( \hat{x} = \hat{t} = 0 \). The general form of \( s \) is given by

\[
s(x, t) = (x - a - (b - a)t/\tau) \sigma
\]

where \( \sigma \) is a real constant. W.l.o.g. let \( \sigma = 1 \). Then a direct computation gives that

\[
\int \int_{\Omega} s(x, t) dxdt = -\frac{\tau}{6} (a^2 + ab + b^2) = \omega s(0, \frac{\tau}{2})
\]

Equation (64) may be interpreted as a special quadrature rule with node \( (\hat{x}, \hat{t} + \tau/2) \). We have chosen this node because it appears also in the quadrature rule for the fluxes treated in Section 4.5 above, so we can minimize the evaluations of the solution \( w \).

In the following we apply the lemma to the four cases. Let \( \overline{\Omega} \) be the region covered by the granular material. First, we compute the integral over the intersection of \( \overline{\Omega} \) with the union of the \((f - 1/2)^{th}\) and the \((f + 1/2)^{th}\) cell, \( \Omega = \overline{\Omega} \cap ([x_{f-1}, x_{f+1}] \times [t^n, t^{n+1}]) \). Using \( \hat{x} = x_{f-1}, \hat{t} = t_n, a = x_{F_{f-1}}^{n} - x_{f-1}, b = x_{F_{f+1}}^{n+1} - x_{f-1} \) and \( \tau = \Delta t \) in Lemma 4.1 gives

\[
\int_{t_n}^{t_{n+1}} \int_{x_{f-1}}^{x_{f+1}} s(x, t) dx dt = \omega_{f-1} s_{f-1}^{n+1/2}
\]

with

\[
\omega_{f-1} = \frac{\Delta t (x_{F_{f-1}}^{n} - x_{f-1})^2 + (x_{F_{f-1}}^{n} - x_{f-1})(x_{F_{f+1}}^{n+1} - x_{f-1}) + (x_{F_{f+1}}^{n+1} - x_{f-1})^2}{x_{F_{f-1}}^{n} + x_{F_{f+1}}^{n+1} - 2x_{f-1}}.
\]

Similarly, for the integral over \( \overline{\Omega} \cap ([x_{f}, x_{f+1}] \times [t^n, t^{n+1}]) \) we obtain

\[
\int_{t_n}^{t_{n+1}} \int_{x_{f}}^{x_{f+1}} s(x, t) dx dt = \omega_{f} s_{f}^{n+1/2}
\]
where $\bar{t} = t^{n+1/2}$ in cases I and II and $\bar{t}$ is given by (61) in cases III and IV, and the weight is given by

$$\omega_f = \begin{cases} 0 & \text{in case I} \\ \frac{\Delta t (x_{F_1}^n - x_f)^2 + (x_{F_1}^n - x_f)(x_{F_1}^n + x_f^n - x_f)^2}{x_{F_1}^n + x_{F_1}^n - 2x_f} & \text{in case II} \\ \frac{-\Delta t}{4} (x_{F_1}^{n+1} - x_f) & \text{in case III} \\ \frac{-\Delta t}{4} (x_{F_1}^{n+1} - x_f) & \text{in case IV} \end{cases}$$

Here $\Delta t$ is given by (62). The integral over $[x_{f-1}, x_f] \times [t^n, t^{n+1}]$ is then computed by subtracting the integral over $[x_f, x_{f+1}] \times [t^n, t^{n+1}]$ from that over $[x_{f-1}, x_{f+1}] \times [t^n, t^{n+1}]$,

$$\int_{t^n}^{t^{n+1}} \int_{x_{f-1}}^{x_f} s(x, t) \, dx \, dt = \omega_{f-1} s_{f-1}^{n+1/2} - \omega_f s_f. \quad (69)$$

This completes the definition of the quadrature rules for the three integrals on the RHS of (50). It remains to extrapolate the solution $w$ to the new quadrature point $(x_f, \bar{t})$ near the front.

### 4.7. Determination of the physical quantities at $\bar{t}$

In cases III and IV the margin point passes the cell boundary $x_f$ at $t^*$ and goes into the neighbouring cell. The outflow in case III and the inflow in case IV through the cell boundary at $x_f$ as well as the source term in the new and old margin cells are essential for determining the cell average of the margin cells in the front-tracking method.

In case III the physical quantities flow through the boundary $x_f$ into the $(f + 1)^{th}$ cell during the time interval $[t^*, t^{n+1}]$. The outflow is approximated by the value at $(x_f, \bar{t})$, where $\bar{t} = \frac{1}{4}(t^{n+1} + t^*)$, which is determined by using Taylor series expansion at the point $(x_{F_1}^n, t^n)$ with respect to space and time. Using the margin-cell-reconstructed slopes and the mass balance equation (1), the avalanche depth $h$ at $(x_f, \bar{t})$ is then given by

$$h_f^\bar{t} = h_{F_1} + \frac{\partial h}{\partial x} \bigg|_{(x_{F_1}, t^n)} (x_f - x_{F_1}^n) + \frac{\partial h}{\partial t} \bigg|_{(x_{F_1}, t^n)} (\bar{t} - t^n)$$

$$= \frac{\partial h}{\partial x} \bigg|_{(x_{F_1}, t^n)} (x_f - x_{F_1}^n) - \frac{\partial m}{\partial x} \bigg|_{(x_{F_1}, t^n)} (\bar{t} - t^n)$$

$$= (\sigma^h f)(x_f - x_{F_1}^n) - (\sigma^m f)(\bar{t} - t^n),$$

$$= (\sigma^h f)[(x_f - x_{F_1}^n) - u_{F_1}(\bar{t} - t^n)],$$

where $(\sigma^h f)$ and $(\sigma^m f)$ are the slopes of the margin cell reconstructions defined in §4.1, and we have used the relation $(\sigma^m f) = u_{F_1}(\sigma^h f)$. Similarly, the momentum $m_f^\bar{t}$ is approximated by

$$m_f^\bar{t} = m_{F_1} + \frac{\partial m}{\partial x} \bigg|_{(x_{F_1}, t^n)} (x_f - x_{F_1}^n) + \frac{\partial m}{\partial t} \bigg|_{(x_{F_1}, t^n)} (\bar{t} - t^n).$$

$$= m_{F_1} + \frac{\partial m}{\partial x} \bigg|_{(x_{F_1}, t^n)} (x_f - x_{F_1}^n) + \frac{\partial m}{\partial t} \bigg|_{(x_{F_1}, t^n)} (\bar{t} - t^n).$$

$$= m_{F_1} + \frac{\partial m}{\partial x} \bigg|_{(x_{F_1}, t^n)} (x_f - x_{F_1}^n) + \frac{\partial m}{\partial t} \bigg|_{(x_{F_1}, t^n)} (\bar{t} - t^n).$$
Using the cell reconstruction of the margin $f^{th}$ cell and the momentum balance equation (2), equation (71) becomes

$$m^f_t = \frac{\partial m}{\partial x}(x_f - x^n_{P_f}) - \frac{\partial}{\partial x}\left(\frac{m^2}{h} + h^2 \beta_x\right) \quad (\bar{t} - t^n)$$

$$+ h^n_{P_f} s_x(x^n_{P_f})(\bar{t} - t^n)$$

$$= (\sigma^m)^n_f (x_f - x^n_{P_f}) - \left(2m \frac{\partial m}{\partial x} - m^2 \frac{\partial h}{h} \frac{\partial x}{\partial x} + \beta_x h \frac{\partial h}{\partial x} + \frac{h^2 \partial \beta_x}{2} \right) \quad (\bar{t} - t^n)$$

$$= (\sigma^m)^n_f (x_f - x^n_{P_f}) - \left(2u^n_{P_f}(\sigma^m)^n_f - (u^n_{P_f})^2 (\sigma^h)^n_f\right)(\bar{t} - t^n)$$

$$= u^n_{P_f} h^n_{f}.$$  

(72)

In case IV the physical quantities at the boundary $(x_f, \bar{t})$ are determined in the same way, but the time points are defined differently: $\bar{t} = (t^n + t^*)/2$ for case III and $\bar{t} = (t^n + t^*)/2$ for case IV.

### 4.8. Summary of the front-tracking algorithm

The front-tracking algorithm may be summarized as follows:

$$w^{n+1}_{f-1/2} = \frac{1}{2} w^n_{f-3/4} + (1 - \alpha_f) w^n_{f} - \frac{\Delta f}{\Delta x} f^n_j + \frac{\Delta t}{\Delta x} f^{n+1/2}_{f-1}$$

(73)

$$\omega_{f-1} s^{n+1/2}_{f-1} - \frac{\Delta f}{\Delta x} s^n_j$$

$$w^{n+1}_{f+1/2} = \alpha_f w^n_{f} + \frac{\Delta f}{\Delta x} f^n_j + \frac{\Delta f}{\Delta x} s^n_j.$$  

(75)

Here

$$\alpha_f = \begin{cases} 0 & \text{in cases I and III} \\ \left(\frac{x^n_{P_x} - x_f}{x^n_{P_x} - x_{f-1/2}}\right)^2 & \text{in cases II and IV} \end{cases}$$

(76)

$$\Delta t = \begin{cases} 0 & \text{in case I} \\ \Delta t & \text{in case II} \\ t_{n+1} - t^* & \text{in case III} \\ t^* - t_n & \text{in case IV} \end{cases}$$

(77)

$$\bar{t} = \begin{cases} t_n & \text{in case I} \\ t_{n+1/2} & \text{in case II} \\ (t_{n+1} + t^*)/2 & \text{in case III} \\ (t_n + t^*)/2 & \text{in case IV} \end{cases}$$

(78)

The weights $\omega_{f-1}$ and $\omega_f$ are defined in (66) and (68). The values of $w(x_f, \bar{t})$, needed to determine $f^n_j$ and $s^n_j$, are defined in (70) and (72). This completes the definition of the update at the front margin. The tail can be treated completely analogously.
5. NUMERICAL RESULTS

5.1. Travelling shock wave

In this test problem we are concerned with granular flow on a plane ($\lambda \kappa = 0$) inclined chute ($0 \leq x \leq 36$ dimensionless units), where the internal and basal friction angles are both presumed to be equal to the inclination angle, $\phi = \delta = \zeta = 40^\circ$. That implies a non-accelerative flow, $s_x = 0$, whose earth pressure coefficient is constant $K_x = K_{x,act} = K_{x,pass}$. Selecting $\varepsilon = 1$ and using (6) yields $\beta_x = \varepsilon \cos \zeta K_x = 1.84477$. A jump of thickness $H = h^- - h^+ = 3$ with $h^+ = 0.3$, $h^- = 0.9$ is presumed at $x = 24$. By virtue of (12) the velocity difference is then determined, $u^+ - u^- = 1.2148317$, where the positive sign is selected. Since an instability was expected close to $u = 0$ as a singularity by $\text{sgn}(u)$, the downslope velocity is assumed to be $u^- = 0.1$, so that the term $\text{sgn}(u)$ is always unity. The initial condition of this test problem is defined as follows:

$$h(x, 0) = \begin{cases} 0.3, & \text{for } 0 \leq x < 24, \\ 0.9, & \text{for } 24 \leq x < 36, \end{cases}$$  \quad (79)

$$u(x, 0) = \begin{cases} 1.3148317, & \text{for } 0 \leq x < 24, \\ 0.1, & \text{for } 24 \leq x \leq 36. \end{cases}$$  \quad (80)

From (13) the velocity of the upslope travelling wave is then expected as $V_n = -0.50741585$. For the boundary condition a constant inflow at $x = 0$ and an outflow condition for $x = 36$ are introduced.

5.1.1. Lagrangian technique

By the Lagrangian moving grid method the governing equations (1) and (4) are solved by virtue of (34)–(37). The initial depth, $h^0_j$, of the $j^{th}$ element is taken to be the cell average of the exact initial profile. The initial velocity of the boundary, $u^0_j$, is given by the volume weighted velocity of the adjacent cells. They are

$$h^0_j = \frac{\int_{b^0_{j-1}}^{b^0_j} h(x, 0) \, dx}{b^0_j - b^0_{j-1}}, \quad u^0_j = \frac{\int_{c^0_j}^{c^0_{j+1}} h(x, 0) u(x, 0) \, dx}{\int_{c^0_j}^{c^0_{j+1}} h(x, 0) \, dx},$$  \quad (81)

where $b^0_j$ and $b^0_{j-1}$ are the boundaries of the $j^{th}$ cell at $t = 0$, and $c^0_j$ denotes the initial centre of the $j^{th}$ cell.

The constant inflow and outflow boundary conditions are executed by setting the depth gradient $\partial h/\partial x$ at $x = b_0(t)$ and $x = b_N(t)$ equal to zero, so that $\text{du}/\text{dt} = 0 \Rightarrow u_0(t) = u_0(0)$ and $u_N(t) = u_N(0)$ for $t > 0$ because the flow is on an non-accelerating slope $s_x = 0$. Fig. 7 demonstrates the simulated results ($N = 60$); oscillations develop as the shock wave passes through, and these persist even if the time step is selected to be very small. The velocities of the cell boundary after the shock are sometimes faster or slower than they should be and therefore oscillations take place. These oscillations propagate downslope as time increases and no shock wave propagates upslope. This indicates that the Lagrangian moving grid technique is ill behaved and cannot describe the travelling shock wave.
5.1.2. Eulerian shock-capturing methods

The NOC scheme is applied to (1) and (2) on a 1D grid with 90 and 360 gridpoints, respectively. The initial conditions are transferred to the mean values over the cells before the computing commences,

\[ h_j^0 = \frac{1}{\Delta x} \int_{x_{j-1/2}}^{x_{j+1/2}} h(x, 0)dx, \quad u_j^0 = \frac{1}{h_j^0} \int_{x_{j-1/2}}^{x_{j+1/2}} h(x, 0)u(x, 0)dx. \]  

(82)
The constant inflow boundary condition is implemented by the assignments \( h_0(t) = h_0(0) \) and \( m_0(t) = m_0(0) \) at \( x = 0 \). The outflow boundary condition is described by setting \( \partial h / \partial x = 0 \) and \( \partial m / \partial x = 0 \) at \( x = 36 \), where they are

\[
U_N = (4U_{N-1} - U_{N-2}) / 3, \quad \text{for} \quad U = h, m, \tag{83}
\]

by using the cell averages of the closest cells for a second order extrapolation.

Three different cell reconstructions were tested: the NOC scheme with superbee limiter (NOCS-S), piecewise linear \((r=2)\) and quadratic \((r=3)\) WENO reconstructions \([26]\). Fig. 8 demonstrates the simulated avalanche depth of the travelling wave problem (circles) and a comparison with the exact solution (solid line) at \( t = 6 \) dimensionless time units. All of them are able to adequately describe this travelling shock wave problem.

### 5.2. Parabolic similarity solution

This section is concerned with the simulation of the parabolic similarity solution outlined in §2.2. In the test problem the parabolic avalanche body is considered to slide on an inclined flat plane in the domain \( 0 \leq x \leq 36 \) dimensionless length units with constant inclination angle \( \zeta = 40^\circ \). The basal and internal friction angles are simultaneously selected to be \( 30^\circ \), and the initial condition is chosen to be \( g_0 = 1 \) and \( p_0 = 0 \). On the inclined plane the initial depth and velocity distributions are mapped into

\[
\begin{align*}
 h(x, 0) &= 1 - \left( \frac{(x - 4)}{3.2} \right)^2, \\
 u(x, 0) &= 1.2, \\
 &\text{for } x \in [0.8, 7.2]. \tag{84}
\end{align*}
\]

Our choice of the initial velocity, \( u(x, 0) = u_0 = 1.2 \), guarantees that condition \((32)\) will be satisfied for all times. This problem will serve as the standard test problem for the resolution of the depth profile and the determination of the margin locations.

#### 5.2.1. Lagrangian technique

In the Lagrangian moving grid technique the model equations \((1)\) and \((4)\) are solved by virtue of \((34)-(37)\) on a 1D grid. The boundary condition is given by setting the heights at the margin (front and rear) points to be equal to zero, \( h_0(x, t) = 0 \) and \( h_N(x, t) = 0 \).

Fig. 9 illustrates the simulated result at the dimensionless time units \( t = 0, 2, 4, 6 \) with cell number \( N = 16 \), in which the circles denote the computed results and the solid line indicates the exact solution. The avalanche body extends as it flows down and still keeps the parabolic depth profile. The velocity is keeping a linear distribution through the bulk body. It ensures the symmetric depth profile during the motion.

From the simulated results it follows that the Lagrangian moving grid technique can not only describe the depth profile well but also determines the margin locations of the similarity solution very accurately. There is excellent agreement between the simulated results and the exact solutions, see Fig. 9. The motions of the front and rear edges of the avalanche body in the similarity solution are illustrated in Fig. 10. The circles denote the computed results by the Lagrangian moving grid technique
FIG. 9. Depth (left) and the corresponding velocity (right) profiles of the parabolic similarity solution (Problem I) computed by the Lagrangian moving-grid scheme at the dimensionless time units $t = 0, 2, 4, 6$, where the avalanche body is divided into 16 cells, and the time interval is $\Delta t = 10^{-3}$.

FIG. 10. Locations of the front and rear edges of the avalanche body in the parabolic similarity solution problem as they evolve in time. The circles denote the computed results by the Lagrangian moving grid technique ($N = 16$), and the solid lines indicate the exact margin positions. They are in excellent agreement.

and the solid lines indicate the exact locations of the margins. They are also in excellent agreement.

The Lagrangian method is also tested by different grid numbers. Fig. 11 shows the results computed by different grid numbers, $N = 16, 32,$ and $64$, respectively. With different grid numbers this method can always keep the excellent resolutions when compared with the exact solutions.

Calculations were also performed with initial condition $p_0 \neq 0$; results turned out to be similarly convincing as the above ones. For this reason they are not presented here [36].

5.2.2. Eulerian technique
FIG. 11. Depth profiles computed by the Lagrangian moving-grid technique for the parabolic similarity solution problem (Problem I), where the avalanche body is divided into different numbers of cells, \( N = 16, 32, 64 \). All the results are shown at \( t = 6 \) and the computational time interval is \( \Delta t = 10^{-3} \). The number of the cells does not influence the good agreement between the simulated results (circles) and the exact solutions (solid line).

In §3.2, the Eulerian schemes are based on the model equations (1) and (2) in conservative form, so that the velocity outside the avalanche body (inclusive the margin point) is not defined. Intuitively, adding a thin layer of the material over the whole computational domain could be used to treat the grain free regions. Another trick can also be introduced, in which all the physical variables are set to zero if \( h = 0 \). This would be reasonable since \( h = 0 \rightarrow m = hu = 0 \).

Fig. 12 illustrates the comparison between the computed results obtained from the NOC scheme, where a thin layer \( h_0 = 10^{-4} \) respectively \( h_0 = 0 \) is added over the whole computational domain, and from the scheme with our front-tracking method. All the three results of the depth profiles are acceptable except for the oscillation near the top. However, have a look at the velocity profiles in these figures, there are several cells with \( \partial u/\partial x < 0 \) around the margins. This violates the assumption \( \partial u/\partial x > 0 \) in the parabolic similarity solution problem. Moreover, the results show that there is large numerical diffusion around the margins (i.e. the margins move further than they should do) without the front-tracking method. For both reasons, the front-tracking method is needed to determine the location of the margins.

Let us discuss the origin of the oscillation near the center of the avalanche. When one recomputes the solution using unlimited central differences for \( \mathbf{w}' \), the oscillation disappears. Therefore, we have the following paradoxical situation: the introduction of TVD-limiters, which are needed to stabilize the solution in the presence of discontinuities, may destabilize the solutions in smooth regions! In fact, this is not entirely surprising, since in the presence of limiters the fluxes depend only Lipschitz-continuously on the data.
FIG. 12. Depth (left) and velocity (right) profiles of the parabolic similarity solution computed by the NOC scheme with Superbee limiter. In the top panels, a thin layer with $h_0 = 10^{-4}$ is added to the whole computational domain. In the middle panels, all physical variables are set to zero if $h = 0$. Whilst, the bottom panels demonstrate the results from the scheme with front-tracking method. The whole computational domain is divided into 90 cells ($N = 90$), the circles denote simulated results and the solid lines represent the exact solution. The results show that the added thin layer does not influence the depth profile very much, if it is sufficiently small, but the margin locations can not be exactly determined without the front-tracking method. An oscillation near the middle of the avalanche (local maximum) is visible in all three calculations.

FIG. 13. Depth (left) and velocity (right) profiles of the parabolic similarity solution at $t = 6$ computed by the NOC scheme with front-tracking and piecewise quadratic WENO cell reconstruction. The whole computational domain is divided into 90 cells ($N = 90$) and the Courant number is selected to be 0.3. The margin locations are well described and the oscillation near the center is successfully removed.

We have therefore experimented with more smooth reconstructions, namely piecewise quadratic WENO interpolants of Jiang and Shu [17] and Levy, Puppo and
FIG. 14. Front and rear edges of the avalanche body in the parabolic similarity solution simulated by the NOC-front-tracking scheme as they evolve in time. “◦” denotes the computed results obtained with the piecewise quadratic WENO cell reconstruction, “×” means the results deduced with Superbee limiter and solid lines indicate the exact margin solution.

Russo [26], which depend smoothly on the data and are at the same time nonoscillatory at discontinuities. In the margin cells, we still use the piecewise linear reconstructions introduced in Section 4.1, and in the two cells adjacent to the margin cells, we use a piecewise linear WENO reconstruction. We have experimented both with second- and third-order quadrature rules in time. In our experience, both yield comparable results. Fig. 13 demonstrates the results for these reconstructions combined with our front-tracking method. The margin locations are well described by the front-tracking method, and the oscillation near the center is successfully removed (compare the bottom panels in Fig. 12 and Fig. 13).

Fig. 14 shows the computed front and rear edges of the avalanche body in the parabolic similarity solution as they evolve in time. “◦” denotes the computed results obtained by the NOC scheme with the piecewise quadratic WENO cell reconstruction, “×” means the results deduced with Superbee limiter and solid lines indicate the exact margin solution. Both the Superbee limiter and the piecewise quadratic WENO cell reconstruction for the NOC front-tracking schemes can yield good agreement of the determined margin locations with the exact solutions.

The use of the Superbee limiter results in a small delay of the avalanche body, i.e. a slower velocity both at the front and the rear. The reason is that the Superbee limiter tends to be overcompressive in smooth regions of the solution, and therefore it does not give the appropriate flux at the boundaries between the internal and the margin cells.

In order to obtain some quantitative information on the accuracy of the schemes, we introduce an error measure for the depth by

\[
E = \frac{\sum_{j=0}^{N} \left| h_j - h_j^{\text{exact}} \right|}{\sum_{j=0}^{N} h_j^{\text{exact}}}; \tag{85}
\]
 TABLE 5.1
Error (85) of the different schemes.

|        | NFT(S90) | NFT(W90) | NFT(S360) | NFT(W360) | Lag(16) | Lag(32) |
|--------|----------|----------|-----------|-----------|---------|---------|
| $t = 1$ | 9.0247   | 7.6096   | 0.8816    | 0.8813    | 1.7130  | 0.2937  |
| $t = 2$ | 11.3333  | 7.5679   | 0.8532    | 0.9024    | 1.7764  | 0.3664  |

| $t = 8$ | 15.3966  | 6.0762   | 1.8558    | 1.1981    | 1.9526  | 0.4830  |

where $\overline{h}_j^{\text{exact}}$ denotes the $j$th cell averaged depth of the exact solution. The errors of the Lagrangian method, the NOC front-tracking scheme with Superbee limiter (NFT(S)) and piecewise quadratic WENO interpolations (NFT(W)) at $t = 1$ to 8 dimensionless time units are shown in Table. Here, the Eulerian schemes are tested by using $N = 90$ and $N = 360$, respectively, and for the Lagrangian scheme $N = 16$ and $N = 32$ are used. The Lagrangian method results in the least errors, obviously smaller than all the Eulerian schemes. It also converges at a better rate.

5.3. Upward Moving Shock Wave

Shock formations are often observed when the avalanche slides into the run-out horizontal zone. Here the front part comes to rest, while the tail accelerates further and its velocity becomes supercritical. In [38] a comparison was made between our shock-capturing method and the Lagrangian moving grid technique for the case of coinciding basal and internal friction angles. Here we compute a flow with basal friction angle $\phi = 38^\circ$ and internal friction angle $\delta = 35^\circ$. As a consequence, we have a jump in the earth-pressure coefficient $K_x$ when the flow changes from an expanding ($u_x > 0$) to a contracting region ($u_x < 0$).

The setup is as follows: The granular material released from a parabolic cap slides down an inclined plane and merges into the run-out horizontal zone. The centre of the cap is initially located at $x = 4.0$ and the initial radius and the height are 3.2 and 1.0 dimensionless length units, respectively. The inclination angle of the inclined plane is $40^\circ$ and the (linear and continuous) transition region lies between $x = 21.5$ and $x = 25.5$. We use 180 gridpoints and a CFL-number of 0.4.

Fig. 15 illustrates the simulated process as the avalanche slides on the inclined plane into the run-out horizontal zone (so initially the flow is expanding). The avalanche body extends on the inclined plane until the front reaches the run-out zone. Here the basal friction is enough to bring the front of the granular material to rest while the rear part accelerates further. Therefore, the flow becomes contracting in the transition zone. At this stage, a shock (surge) wave is created ($t = 12$),
which moves upward. Such shock waves make the Lagrangian method unstable, if no artificial viscosity is applied (see [38]). Our non-oscillatory central front-tracking scheme handles both the shock wave and the margins of the avalanche well.

6. CONCLUSION

In this paper we have developed a Lagrangian and an Eulerian shock-capturing finite-difference scheme with front-tracking for the spatially one-dimensional Savage-Hutter equations of granular avalanches. The purpose was to reproduce the temporal evolution of the avalanche geometry and downslope velocity under situations when internal shocks may occur. This happens e.g. when an avalanche of finite mass moves from an inclined chute into the horizontal run-out zone and, in the transition zone, is decelerated from a supercritical flow state to a subcritical state. The Lagrangian scheme (which is excellent for smooth solutions) develops unphysical oscillations when the solution contains, or develops, shock discontinuities. In order to compute discontinuous solutions, we propose to use a conservative shock-capturing finite difference scheme. We adapt the second-order accurate staggered...
scheme of Nessyahu and Tadmor [30] to the Savage-Hutter equations. The staggered approach avoids the use of characteristic decompositions which are needed in standard upwind schemes, but are not known for the Savage-Hutter equations. We show that our non-oscillatory central (NOC) scheme reproduces both smooth and shock solutions adequately except for the following two problems: First, oscillations may occur near smooth extrema due to the presence of piecewise linear reconstructions with TVD-type limiters. These oscillations disappear when one uses piecewise quadratic cell reconstructions in the interior of the avalanche. Second, our NOC scheme (and in fact, any Eulerian scheme) does not capture the vacuum-boundary accurately. This may lead to serious stability problems. We improve the treatment of the free boundary by combining the scheme with a front-tracking method applied to the margin cells. In the spirit of the Nessyahu-Tadmor scheme, we do not make use of the vacuum Riemann-problem, but rely on a new piecewise linear reconstruction at the vacuum boundary and carefully chosen Taylor-extrapolations for the corresponding numerical fluxes. With such a combination of an internal Eulerian NOC scheme and a Lagrangian “boundary scheme” two standard test problems – an upward moving shock and a parabolic cap moving down an inclined plane – could be well reproduced. The scheme also produces satisfactory results for the more realistic problem mentioned above: an avalanche moving down an inclined plane and coming to rest at a flat run-out. Here an upward moving shock wave develops from smooth data, and the flow changes from being expanding to contracting ahead of the shock. In this situation, the earth pressure coefficient changes discontinuously, so we are facing the full difficulties inherent in the Savage-Hutter model.

Several questions remain and await further study:

- The shock-capturing NOC numerical method including the front-tracking scheme should be extended to two-dimensional flows. This is work under progress.
- The original Lagrangian moving grid scheme could also be developed as a shock-capturing scheme. Here the main difficulty would be in the determination of the correct grid velocity.

We are working on these topics and will report on results in due time.
