ABSTRACT

We report the statistics of the number of active regions (NAR) observed at 17 GHz with the Nobeyama Radioheliograph between 1992, near the maximum of cycle 22, and 2013, which also includes the maximum of cycle 24, and we compare with other activity indexes. We find that NAR minima are shorter than those of the sunspot number (SSN) and radio flux at 10.7 cm (F10.7). This shorter NAR minima could reflect the presence of active regions generated by faint magnetic fields or spotless regions, which were a considerable fraction of the counted active regions. The ratio between the solar radio indexes F10.7/NAR shows a similar reduction during the two minima analyzed, which contrasts with the increase of the ratio of both radio indexes in relation to the SSN during the minimum of cycle 23–24. These results indicate that the radio indexes are more sensitive to weaker magnetic fields than those necessary to form sunspots, of the order of 1500 G. The analysis of the monthly averages of the active region brightness temperatures shows that its long-term variation mimics the solar cycle; however, due to the gyro-resonance emission, a great number of intense spikes are observed in the maximum temperature study. The decrease in the number of these spikes is also evident during the current cycle 24, a consequence of the sunspot magnetic field weakening in the last few years.

Key words: Sun: activity – Sun: magnetic fields – Sun: radio radiation

1. INTRODUCTION

The unusually low level of solar activity, inferred by different indexes during cycle 24, launched new discussions concerning the future behavior of the Sun. The oldest and most famous solar activity index is the counting of dark regions on the solar surface, comprising the so-called sunspot number (SSN). A sunspot appears because of the obstruction of convective movement that occurs at the base of the photosphere due to the existence of a strong magnetic field in the region. Thus, the SSN index is associated only with photospheric features of the solar magnetic variability.

Penn & Livingston (2006) determined that the minimum magnetic field intensity necessary for sunspot formation is 1500 G and also suggested that there is, on average, a linear decrease in the sunspot maximum magnetic field intensity occurring along the cycles. This reduction was confirmed in a recent study, which shows that the maximum magnetic field intensities of sunspots during the period of 1998–2002 have a normal distribution with a mean of 2436 ± 26 G and a width of 323 ± 20 G, while during the period 2008–2011, the mean value dropped to 1999 ± 13 G and a width of 276 ± 9 G (Livingston et al. 2012). An alternative interpretation proposed by Nagovitsyn et al. (2012) suggested that the mean magnetic field reduction could be explained by a gradual decrease in the number of large sunspots, while the number of small ones increased.

Another classical index used to measure solar activity is the 10.7 cm daily mean radio flux (hereafter referred as F10.7), which is generated at coronal heights and related to the presence of active regions and the occurrence of flares. During cycle 24, F10.7 also showed a decrease compared to previous cycles. However, its reduction rate is different from the SSN decrease, destroying the linear relation traditionally assumed to exist between these two solar indexes and making the prediction of SSN based on F10.7 to be overestimated in the last two cycles (Hathaway 2010; Livingston et al. 2012).

Since the radio emission of non-flaring active regions in the cm range depends on free–free radiation from the hot plasma trapped in the magnetic field loops and from the gyro-resonance radiation due to strong magnetic fields, the results obtained by Livingston et al. (2012) suggest that the presence of magnetic fields is still contributing to F10.7, i.e., the magnetized regions are still emitting at radio frequencies even though the magnetic field is not strong enough to generate a sunspot.

At 17 GHz, the gyro-resonance emission from active regions overcomes the free–free radiation when the third harmonic (associated with magnetic field intensities of 2000 G) is produced in the transition region or at coronal heights (Shibasaki et al. 2011), which results in high brightness temperature: above 10 times the quiet Sun values (TsB ≳ 105 K; Gelfreikh 1999). Thus, the active region maximum brightness temperatures observed at 17 GHz should reflect the magnetic field reduction reported by Livingston et al. (2012).

To investigate the relationship between SSN and F10.7, we report a statistical analysis of the number of active regions (hereafter referred to as NAR) measured in the 17 GHz maps obtained since 1992 by the Nobeyama Radioheliograph (NoRH; Nakajima et al. 1994).

2. DATA ANALYSIS AND RESULTS

The NoRH has been obtaining daily solar maps at 17 GHz with 15 arcsec resolution since 1992. Its database provides an unprecedented opportunity to perform statistical studies at radio frequencies, such as the analysis of the variation of solar radius...
Figure 1. Latitude positions of the 17 GHz active regions detected in the analysis. The color scale represents the active region maximum brightness temperature ($T_B < 1 \times 10^5 \text{ K}$).

(A color version of this figure is available in the online journal.)

and polar brightening along the solar cycle (Selhorst et al. 2011; Gopalswamy et al. 2012). In this work, we calculate the daily NARs observed in Nobeyama 17 GHz maps and compare the results with the SSN and the 10.7 cm radio flux ($F_{10.7}$).

The identification of each active region in the 17 GHz maps was automatized using computerized procedures. To avoid small bright features dispersed over the solar disk, as weak as the polar bright patches, the following criteria were adopted:

1. size greater than 150 pixels$^2$ ($\sim$300 MSS (millionth of solar surface));
2. latitudes between $-45^\circ$ and $+45^\circ$; and
3. maximum brightness temperature ($T_{B_{\text{max}}}$) at least 40% greater than the quiet Sun value;
4. discard active regions at the limb.

For the studied period (1992–2013), almost 7500 maps were analyzed, in which more than 16,000 active regions were detected by the method described above. During this period, only five false active regions generated by prominence eruption (PE; Gopalswamy & Yashiro 2013) were detected and removed by visual inspection, none of them occurring during minima periods. This low count is consistent with the statistic of 1.4 PEs per month during the rise phase of the 22–23 minimum and of 0.5 PEs for the 23–24 minimum (Gopalswamy et al. 2012).

Moreover, the possible contamination will become statically negligible, since the large-scale brightening caused by the PEs is shorter than the interval between the daily NoRH maps used here, all of which were obtained at the same time (local midday).

Figure 1 shows the latitude positions of the 17 GHz active regions as a function of time, where the color scale represents the maximum brightness temperature that saturates at $T_B = 1 \times 10^5$ K. As expected, the NAR latitude distribution follows the butterfly diagram. The majority of active regions are cooler than $4 \times 10^4$ K, which is compatible with bremsstrahlung as the main mechanism emission Selhorst et al. (2008).

The NAR monthly average is plotted in Figure 2(a), along with $F_{10.7}$ and SSN monthly means (Figures 2(b) and (c), respectively). Although the NAR also mimics the solar cycle, one can see small discrepancies between the NAR and the classical solar index plotted on Figure 2, in which the thick line represents a running mean of 1 year (12 points).

To quantify these differences, ratios between the yearly running mean of the three indexes are plotted in Figure 3. In all panels, the dots were used for the months with SSN $> 10$, whereas the triangles and asterisks represent the months with $1 \leq \text{SSN} \leq 10$ and $0 \leq \text{SSN} < 1$, respectively, that is, minimum activity. The ratio between $F_{10.7}$ and SSN
(Figure 3(a)) shows distinct behavior during the two minima analyzed. This ratio is reduced during the cycle minimum 22–23, but increases during the quietest months of the cycle 23–24 minimum. On the other hand, the ratio $F_{10.7}/NAR$ shows a similar reduction during both minima (Figure 3(b)). The ratio between the yearly NAR and SSN running means, plotted in Figure 3(c), shows an increase during both minima intervals, and reaches its highest level during the prolonged minimum between the cycles 23 and 24 (2008–2010).

The two minima of the radio indexes ratio ($F_{10.7}/NAR$) are similar, whereas the minima of the ratios $F_{10.7}/SSN$ and NAR/SSN clearly change. These differences can be due to the great reduction observed in the SSN during the prolonged last minimum. For example, during minimum 22–23, there was only one month with a monthly average SSN of less than 1, while during minimum 23–24, five months had SSN $< 1$ (Figure 2).

Moreover, a small time lag exists between the ratios $F_{10.7}/SSN$ and NAR/SSN (Figures 3(a) and (c), respectively), which could be caused by the phase shift in the north–south SSN maxima observed (see, e.g., Hathaway 2010) that is indistinguishable in the total solar flux measured by $F_{10.7}$.

For the six months with SSN $< 1$, $F_{10.7}$ remains almost constant, with a mean value of $F_{10.7} = 61.6 \pm 0.9$ Wm$^{-2}$ Hz$^{-1}$, and the monthly NAR never drops to zero. Moreover, the presence of spotless active regions (see, e.g., Gary et al. 1990) were commonly observed during these low activity months. During the quietest period observed (2008–2009), there were 329 active regions counted and 109 (33%) of those were identified on days without sunspots. These results indicate that the $F_{10.7}$ excess with respect to SSN reported for the last cycles could be due to the increase in the relation between NAR and SSN (Figure 3(c)). Moreover, the active regions responsible for the $F_{10.7}$ during both minima were formed at the same rate, instead of the reduction in the sunspot formation rate.

Considering that the main emission mechanisms of non-flaring active regions at 17 GHz are free–free and the gyro-resonance radiation formed at the third harmonic of the gyro-frequency (Selhorst et al. 2008; Shibasaki et al. 2011), one can expect a reduction in the maximum brightness temperature observed at 17 GHz following the reduction of the magnetic field intensity observed in sunspots during the current cycle (Penn & Livingston 2006; Schad & Penn 2010). To verify this assumption, monthly averages of the active region mean and maximum brightness temperatures were calculated. To avoid the high brightness temperatures related to flares, and also considering that the gyro-resonance mechanism can increase the temperatures to values close to $5 \times 10^4$ K (Selhorst et al. 2009), our analysis was restricted to active regions with $T_{brn} < 6 \times 10^4$ K, neglecting only around 0.7% of the total active regions selected.

The result of the brightness temperature analysis is shown in Figure 4. While the variation of the mean brightness temperatures smoothly mimics that of solar cycle (Figure 4(a)), the maximum temperature values show a great number of intense spikes (Figure 4(b)). Since some active regions can be visible on the solar disk for more than 10 days, the presence of these active regions with gyro-resonance contribution increases the maximum brightness temperature average, which appears as intense spikes above the mean values. In Figure 4, this is shown during only two months of the current cycle (after 2009) $T_{brn} > 5 \times 10^4$ K, in contrast with the 27 months of the period between 1998 and 2007.

Curiously, some intense spikes occurred between 2006 and 2007, when the number of sunspots were very low. Nonetheless, this period coincides with an increase of the relative number of large and intense sunspots (Nagovitsyn et al. 2012). After that, the percentage of large sunspots reduces while the number of small ones increases (Nagovitsyn et al. 2012).

3. DISCUSSION AND CONCLUSIONS

The NoRH has been daily observing the Sun for over two decades, which makes the statistical study presented here possible. The long solar minimum observed between cycles 23 and 24 raised some new information concerning quiescent solar behavior, such as the existence of active regions at 17 GHz without photospheric sunspots. This evidence indicates that the lower limit of magnetic fields for active region formation at 17 GHz is smaller than that necessary for sunspot formation inferred by Penn & Livingston (2006).

Comparing the $F_{10.7}$ and SSN monthly averages, Livingston et al. (2012) reported that the difference between the predicted and the observed SSN reflects the reduction in the umbra magnetic field intensity observed in the last 20 yr. This divergence indicates that the magnetic regions are still there; however, the magnetic fields are not strong enough to generate sunspots. To determine the lower limit of the magnetic field intensity to create an active region at 17 GHz, the ratios $F_{10.7}/SSN$ and $F_{10.7}/NAR$ were calculated throughout the cycle. The ratio
between the solar radio indexes $F_{10.7}$ and NAR follows a similar reduction during the two minima analyzed (Figure 3(b)). On the other hand, the reduction observed in the ratio $F_{10.7}/$SSN during the minimum 22–23 is not observed in the prolonged minimum 23–24 (Figure 3(a)). This change can be due to the absence of sunspots during long periods of the cycle 23–24 minimum, while active regions are detected. For this reason, the ratio NAR/SSN increased (Figure 3(c)), i.e., active regions were formed with a lower number of sunspots, and occasionally without them (Gary et al. 1990). Actually, the presence of spotless regions were quite common during the prolonged minimum; for example, 33% of active regions counted in 2008–2009 were observed on days without sunspots. Furthermore, according to our results, it is also possible to deduce that the minimum photospheric magnetic field intensity necessary to form the 17 GHz active regions is $<1500$ G, which is the minimum to form sunspots.

Complementary to the active region magnetic field measurements, the analysis of active region maximum brightness temperatures clearly reflects the magnetic field intensity decrease reported by Livingston et al. (2012), which could be due to a decrease in the number of large and intense sunspots accompanied by an increase in the number of small ones (Nagovitsyn et al. 2012). At 17 GHz, the active region brightness temperatures can reach values of $T_B > 10^5$ K if the third harmonic of gyro-resonance (2000 G) occurs above the transition region (Gelfreikh 1999). The occurrence of these intense active regions was strongly reduced in the current maximum, which is reflected in the low number of months with mean brightness temperatures above $5 \times 10^4$ K shown in Figure 4(b).

Taking into account that gyro-resonance emission at 17 GHz needs a minimum magnetic field intensity of 2200 G at photospheric levels (Vourlidas et al. 2006), if the predictions made by Livingston et al. (2012) for the magnetic field intensity for the period of 2012–2016 are confirmed, it is probable that hot active regions ($T_B > 10^5$ K) will almost disappear from the solar maps at 17 GHz.

Henney et al. (2012) propose a method to forecast $F_{10.7}$, estimating empirically the future global photospheric magnetic field using the flux transport model ADAPT. Nonetheless, this method has many unknowns, mostly derived from the lack of spatial observations at 10.7 cm wavelengths. Since we have shown in this paper that $F_{10.7}$ and NAR correlate well, the Nobeyama 17 GHz daily maps may be used to better constrain the forecasting method proposed by Henney et al. (2012) as an alternative to the lack of solar maps at 10.7 cm, with the advantage that we have good spatial information and a 20 yr long database at 17 GHz.
