(Dated: March 30, 2022)

The measured pseudorapidity distribution of primary charged particles in minimum-bias d + Au collisions at $\sqrt{S_{NN}} = 200$ GeV is presented for the first time. This distribution falls off less rapidly in the gold direction as compared to the deuteron direction. The average value of the charged particle pseudorapidity density at midrapidity is $dN/d\eta|_{|\eta|<0.6} = 9.4 \pm 0.7$ (syst) and the integrated primary charged particle multiplicity in the measured region is $82 \pm 6$ (syst). Estimates of the total charged particle production, based on extrapolations outside the measured pseudorapidity region, are also presented. The pseudorapidity distribution, normalized to the number of participants in d + Au collisions, is compared to those of Au + Au and p + p systems at the same energy. The d + Au distribution is also compared to the predictions of the parton saturation model, as well as microscopic models.

PACS numbers: 25.75.-q, 25.75.Dw

The pseudorapidity distribution of charged particles in d + Au collisions is important for understanding the evolution of the system created in more complicated Au+Au collisions, and may provide a constraint on the initial state parton density. The energy and centrality dependence of RHIC and semi-classical QCD. Measurements of d + Au collisions may be the ideal way to search for the onset of gluon saturation, since the system should be much simpler than the one studied in Au + Au collisions. The results of d + Au collisions are therefore crucial for testing the saturation approach.

In this Letter we present the first measurement of the minimum-bias pseudorapidity distribution of primary charged particles $dN/d\eta$ produced in collisions of deuterons with gold nuclei at a nucleon-nucleon center-of-mass energy, $\sqrt{S_{NN}}$, of 200 GeV. The pseudorapidity, $\eta$, is defined as $\eta = -\ln [\tan(\theta/2)]$, where $\theta$ is the emission angle relative to the direction of the deuteron beam. The data were obtained with the PHOBOS detector at the Relativistic Heavy Ion Collider at Brookhaven National Laboratory. The data were collected using the multiplicity array, covering $|\eta| \leq 5.4$. The array consisted of a barrel of silicon detectors surrounding the beam pipe in the central rapidity region (“Octagon”), and six forward silicon counters, three on each side of the interaction point (“Rings”). The multiplicity array used in d + Au collisions was the same as that for Au + Au collisions at $\sqrt{S_{NN}} = 200$ GeV. The detector setup also included two sets of 16 scintillator counters, covering $3 < |\eta| < 4.5$. These counters were used in the primary event trigger and in the offline event selection.

The results presented in this Letter were obtained by two analysis methods: a “hit-counting” method and an “analog” method. The details of the analysis procedure of the two methods leading to the measurement of $dN/d\eta$ can be found in Ref. 1. The measured pseudorapidity distribution was corrected for particles which were absorbed or produced in the surrounding material and for feed-down products from weak decays of neutral strange particles. Uncertainties associated with these corrections, which we take as 20–50% of the corrections, dominate the systematic errors.

Due to the low multiplicity in d + Au, a new algorithm for collision vertex reconstruction was developed, using the hit position and energy deposited in the Octagon...
In order to determine the minimum-bias pseudorapidity distribution for this analysis, it is necessary to correct for the trigger and vertex finding efficiencies. Since these efficiencies are functions of multiplicity (and therefore centrality), the most model-independent approach is to measure the pseudorapidity distribution in narrow bins of centrality and then integrate over centrality to produce a minimum-bias result. The alternative approach of multiplying by a global Monte-Carlo (MC) correction factor (reconstructed/true MC) would rely on our model to get the details of the shape and the centrality dependence right. To further reduce the model-dependence, we used five different measures for estimating the collision centrality based on the multiplicity (defined by the energy deposited in the silicon detectors) in different regions of pseudorapidity. The first of these centrality measures, \( E_{\text{Tot}} \), used data from the full pseudorapidity coverage of PHOBOS, \(|\eta| \leq 5.4 \). The second measure, \( E_{\text{Oct}} \), used data from the more central region \(|\eta| \leq 3 \). The next two measures, \( E_{\text{AuDir}} \) and \( E_{\text{Edir}} \), used data from the cold direction \((-5.4 \leq \eta \leq -0.5 \) and deuteron direction \((0.5 \leq \eta \leq 5.4 \) ), respectively. The final centrality measure, \( E_{\text{Ring}} \), used data far from the mid-rapidity region from the silicon ring counters at \( 3.0 \leq |\eta| \leq 5.4 \).

The centrality measures were calibrated using HIJING [10] and GEANT 3.21 simulations. In the case of \( E_{\text{Tot}} \), \( E_{\text{Oct}} \), \( E_{\text{AuDir}} \) and \( E_{\text{Edir}} \), the distributions in data and MC were very similar once the triggering and event selection were applied to the MC and an additional scaling factor near unity was included. For instance, for \( E_{\text{Tot}} \) this scaling factor was 1.046. This allowed us to use the zero-bias “true” distribution in the MC to divide the data into equal 10% cross-section bins and to estimate the overall trigger and vertex-finding efficiency of \( \sim 83\% \). Based on studies of reconstructed and true pseudorapidity distributions from different Monte-Carlo simulations, we include a global 5% systematic uncertainty on the pseudorapidity distribution in the reported errors. In the case of \( E_{\text{Ring}} \), the MC and data distributions were sufficiently different that the procedure had to be modified. From the calculated efficiencies in each of the MC centrality bins, we could derive how many of the event in each “true” 10% bin would appear in the data. Cuts were then made on the \( E_{\text{Ring}} \) distribution that gave this efficiency-corrected number of events.

Once the efficiency had been calculated and centrality cuts made, we extracted the average number of participating nucleons \( \langle N_{\text{part}} \rangle \) for each centrality bin using HIJING+GEANT. The measured minimum-bias pseudorapidity distribution and the estimated number of participants were obtained by averaging over all centralities for each centrality measure. This averaging was done as the minimum-bias distribution is less sensitive to centrality resolution and multiplicity bias effects than the individual centrality bins. The final distribution was obtained by averaging over the five minimum-bias distributions given by the different centrality measures. The total number of participant nucleons, \( \langle N_{\text{part}} \rangle \), was estimated to be \( 8.1 \pm 0.7 \) (syst). To cross-check the final distribution obtained by using the silicon centrality measures, a further analysis was performed, only requiring at least one hit in one of the scintillator counter arrays. This analysis was consistent within the present systematic uncertainty.

Figure 1 shows the minimum-bias pseudorapidity

![FIG. 1: Minimum-bias pseudorapidity distributions of primary charged particles, dNch/d\( \eta \), measured for d + Au at \( \sqrt{s_{NN}} = 200 \) GeV. a) dNch/d\( \eta \) distributions obtained by explicit integration over centrality bins for each centrality measure. b) Final dNch/d\( \eta \) distribution obtained by averaging over the five minimum-bias distributions. The gray band corresponds to the systematic errors (90% C.L.). The curve corresponds to a triple Gaussian fit to d + Au.](image.png)
The measured distributions of primary charged particles measured for d + Au collisions at $\sqrt{s_{NN}} = 200 \text{ GeV}$ obtained with the five centrality measures described above. The distributions agree to within 5% everywhere. Fig. 1b shows the final result obtained by averaging with equal weights over the five distributions in Fig. 1a. The systematic errors (90% C.L.) are shown as a gray band. The statistical errors are negligible. Fig. 1b clearly shows that the cross section for particle production is largest in the gold direction ($\eta < 0$), and smallest in the deuteron direction ($\eta > 0$). By fitting the gold-side using a Gaussian in the region $-3 \leq \eta \leq -0.5$, the peak centroid was found to be at $\eta \sim -1.9$. This peak position is much closer to mid-rapidity than predicted by the parton saturation model \[7\], see Fig. 3a. It may be interesting to note that a double Gaussian decomposition of the Au+Au distribution at $\sqrt{s_{NN}} = 200 \text{ GeV}$ \[9\] for the 0–6% most central collisions places the Gaussian centroids at $\eta \sim \pm 1.9$, see Fig. 2. The significance of this observation is, however, not obvious, and may indeed be accidental.

For d + Au, the measured average value of the charged particle pseudorapidity density at midrapidity is $\langle dN_{ch}/d\eta \rangle_{|\eta| \leq 0.6} = 9.4 \pm 0.7 \text{(syst)}$ and the integrated primary charged particle multiplicity in the measured region is $N_{ch}^{0 \leq |\eta| \leq 0.4} = 82 \pm 6 \text{(syst)}$. Since $dN_{ch}/d\eta$ falls off to only about half of its maximum value at the most negative pseudorapidity of the detector acceptance, it is non-trivial to estimate the total charged particle multiplicity, $N_{ch}$, for this system. However, using a triple Gaussian fit to the data we obtain the solid curve in Fig. 1b, which corresponds to a total number of produced charged particles of $N_{ch}^{\text{tot}} = 99$ and the fit of the upper limit of the systematic errors (upper limit of the gray band) gives $N_{ch} = 110$. We believe, however, that this represents an extreme upper limit for $N_{ch}$ since experimental data on p+A multiplicity distributions at lower energies \[11, 12, 13, 14, 15\], as well as various theoretical models discussed below, indicate that the fall-off at large negative pseudorapidities is more abrupt than
indicated by this fit to the data. A more reasonable extrapolation, guided by the expectations based on lower energy p+A data and predictions of the AMPT model, yields an estimate of \( N_{ch} = 5 \) in the extrapolated region. Therefore, we estimate that the total charged particle multiplicity in this reaction is \( N_{ch} = 87^{+23}_{-07} \). It should be kept in mind, however, that even this estimate contains a significant contribution from the unmeasured region of pseudorapidity.

Figure 2 shows the normalized minimum-bias \( dN_{ch}/d\eta \) distribution for d + Au in comparison to the most central (0–6%) Au + Au collisions 5 and non-single-diffractive p + \( \bar{p} \) collisions from UA5 6 at the same energy, \( \sqrt{s_{NN}} = 200 \) GeV. To be consistent with our previous Au + Au pseudorapidity distribution publications, we have used a normalization factor of \( \langle N_{part}/2 \rangle \) which is unity for p + \( \bar{p} \). The distributions from different systems are normalized chiefly to enable a comparison of their shapes. The distribution seen in d+Au collisions at RHIC has features similar to those seen in p+A collisions at lower energies 7–11. Compared to p+\( \bar{p} \) collisions, there is a significant increase in particle production in the gold fragmentation region and a reduction of particle production at positive pseudorapidity in the deuteron direction. The overall normalized production of particles is approximately the same as in proton-(anti-) proton collisions 12.

Figure 3 shows a comparison of the measured minimum-bias pseudorapidity distribution to the published predictions of the parton saturation model 7 and the results from RQMD 17. It is evident that these models are inconsistent with the data. The parton saturation model overestimates the height of the gold-side peak, underestimates its width, and predicts the peak at \( \eta \sim -3 \) rather than \( \eta = -1.9 \) as in the data. On the deuteron side, the model underestimates the charged particle production. RQMD drastically underpredicts the particle production and has surprisingly little pseudorapidity asymmetry.

Figure 3 presents the comparison of the measured \( dN_{ch}/d\eta \) distribution to the predictions of HIJING 10 and the published AMPT calculation 18. The HIJING calculation (dash-dotted curve) reproduces the deuteron side and the peak of the gold-side, but fails to reproduce the tail in the gold direction (\( \eta < -2.5 \)). The AMPT model uses HIJING for the initial stage of the collision, adding a “popcorn mechanism” for baryon-antibaryon production 18, 10 and final-state interactions (FSI). The solid curve is the default, while the dashed curve excludes FSI. We see that both final-state interactions and the popcorn mechanism appear to broaden the gold-side peak, leading to a moderate increase of the particle multiplicity in the region \( \eta \leq -3.5 \).

The ratio of the model predictions to data is shown in Fig. 3. In summary, the pseudorapidity distribution of charged particles produced in d + Au collisions at \( \sqrt{s_{NN}} = 200 \) GeV has been measured. The distribution is rather broad and peaked in the gold direction similar to observations in p+A collisions at lower collision energies. The measured pseudorapidity distribution is compared with the predictions of the parton saturation model as well as microscopic models. While AMPT predictions fall close to the data, the saturation model overestimates the asymmetry between particle production in the gold and deuteron hemispheres.
