**Keywords:** iPLA₂, β-cell, apoptosis, autophagy, ceramides, mitochondrial membrane potential, RIP-iPLA₂-Tg, iPLA₂-KO, caspase-3

**Abbreviations:** BEL, bromoelol lactone suicide inhibitor of iPLA₂; cPLA₂, group IV cytosolic phospholipase A₂; DAPI, 4′,6-diamidino-2-phenylindole; ER, endoplasmic reticulum; ESI, electrospray ionization; GPC, glycerophosphocholine; iPLA₂, β; β-isofrom of group VIA calcium-independent phospholipase A₂; iPLA₂-KO, iPLA₂-deficient mice; RIP-iPLA₂-Tg, transgenic mice in which iPLA₂ is overexpressed specifically in pancreatic islet β-cells; ΔΨ, mitochondrial membrane potential; MS, mass spectrometry; NSMase, neutral sphingomyelinase; PERK, ER-stress transducer pancreatic ER kinase; PL₂, phospholipase A₂; SEM, standard error of the mean; SERCA, sarcoplasmic reticulum Ca²⁺-ATPase; SM, sphingomyelin; T1DM and T2DM, type 1 and 2 diabetes mellitus; UPR, unfolded protein response; WT-KO and WT-Tg, age-matched control littersates of iPLA₂-KO and RIP-iPLA₂-Tg mice, respectively

β-cell apoptosis is a significant contributor to β-cell dysfunction in diabetes and ER stress is among the factors that contributes to β-cell death. We previously identified that the Ca²⁺-independent phospholipase A₂ (iPLA₂), which in islets is localized in β-cells, participates in ER stress-induced β-cell apoptosis. Here, direct assessment of iPLA₂ β role was made using β-specific iPLA₂ β overexpressing (RIP-iPLA₂ β-Tg) and globally iPLA₂ β-deficient (iPLA₂ β-KO) mice. Islets from Tg, but not KO, express higher islet iPLA₂ β and neutral sphingomyelinase, decrease in sphingomyelins, and increase in ceramides, relative to WT group. ER stress induces iPLA₂ β, ER stress factors, loss of mitochondrial membrane potential (ΔΨ), caspase-3 activation, and β-cell apoptosis in the WT and these are all amplified in the Tg group. Surprisingly, β-cells apoptosis while reduced in the KO is higher than in the WT group. This, however, was not accompanied by greater caspase-3 activation but with larger loss of ΔΨ, suggesting that iPLA₂ β deficiency impacts mitochondrial membrane integrity and causes apoptosis by a caspase-independent manner. Further, autophagy, as reflected by LC3-II accumulation, is increased in Tg and decreased in KO, relative to WT. Our findings suggest that (1) iPLA₂ β impacts upstream (UPR) and downstream (ceramide generation and mitochondrial) pathways in β-cells and (2) both over- or under-expression of iPLA₂ β is deleterious to the β-cells. Further, we present for the first time evidence for potential regulation of autophagy by iPLA₂ β in islet β-cells. These findings support the hypothesis that iPLA₂ β induction under stress, as in diabetes, is a key component to amplifying β-cell death processes.

**Introduction**

Both types 1 and 2 diabetes mellitus (T1DM and T2DM) are associated with β-cell dysfunction as a consequence of β-cell death due to apoptosis.¹³ Apoptosis can occur not only via extrinsic death receptor or intrinsic mitochondrial pathway but also due to ER stress.¹ The ER, in addition to serving as a cellular Ca²⁺ store, is the site where secretory proteins are synthesized, assembled, folded, and post-translationally modified. Interruption of any of these functions can lead to production of malformed proteins and their accumulation in the ER. When an imbalance between the load of client proteins on the ER and the ER’s ability to process the load occurs, it results in ER stress and the unfolded protein response (UPR).³ Prolonged ER stress, however, can trigger apoptotic factors in the ER,⁴ activate the intrinsic apoptotic pathway,⁵ lead to downstream activation of caspase-3, a protease that is central to the execution of apoptosis,⁶ and induce apoptotic cell death.

Being a site for Ca²⁺ storage, the ER responds to various stimuli to release Ca²⁺ and is therefore extremely sensitive to changes in cellular homeostasis. As a secretory organelle, the β-cells are endowed with highly developed ER, and therefore, have a greater

susceptibility to developing ER stress and several experimental (PERK+/−, Akita, and NOD.k iHEL) and clinical (Wolcott-Rallison and Wolfram syndromes) reports have linked ER stress-induced β-cell apoptosis to the development of diabetes mellitus (reviewed in ref. 9). However, underlying cellular mechanisms that contribute to this process remain to be elucidated.

Ongoing studies in our laboratory suggest that the Ca2+-independent phospholipase A β (iPLA β) participates in ER stress-induced β-cell apoptosis. The iPLA β belongs to the family of PLA s that hydrolyze the sn-2 substituent of membrane phospholipids to release a free fatty acid and a lysophospholipid. Since its initial descriptions in the heart and pancreatic islet β cells, 11,12 iPLA β activation is now thought to contribute to various biological processes in the CNS, skeletal muscle, bone, eye and vascular smooth muscle. Among the many described roles for iPLA β include its involvement in lipid remodeling, cell proliferation and signal transduction (reviewed in refs. 9 and 13). An additional role, first described in human leukemic monocyte lymphoma U937 cells and subsequently in other non-β-cells, is its participation in apoptosis (reviewed in ref. 9).

A potential role for iPLA β in β-cell apoptosis was initially gleaned from observations reported by the Polonsky group. They noted that decreases in MIN6 insulinoma cell survival following exposure to various chemical ER stressors were Ca2+-independent and due to generation of a bioactive metabolite of arachidonic acid. Subsequently, Kudo’s group reported that inhibition of iPLA β, but not of cPLA β or sPLA β, prevented Fas-stimulated death of human leukemic U937 cells.14 Our studies revealed that thapsigargin, which depletes ER Ca2+ stores by inhibiting sarcoplasmic reticulum Ca2+-ATPase (SERCA) Ca2+ pumps causing ER stress, promotes hydrolysis of arachidonic acid from pancreatic islet membrane phospholipids.15 β-cell membranes are enriched in arachidonic-containing phospholipids, and accordingly, thapsigargin-induced accumulation in arachidonic acid was suppressed by a bromoenol lactone (BEL) suicide substrate inhibitor of the iPLA β.16 These observations raised the possibility that iPLA β is activated during ER stress in β-cells.

Subsequent studies in our laboratory demonstrated that iPLA β participates in ER stress-induced β-cell apoptosis and that this process involves iPLA β-mediated increase in neutral sphingomyelinase-catalyzed hydrolysis of sphingomyelins leading to accumulation of ceramides and mitochondrial depolarization. These observations raised the possibility that modulating the activity of iPLA β can be beneficial to β-cell survival and presumably offer a means to ameliorate β-cell apoptosis associated with diabetes mellitus. However, while these observations strengthened a link between iPLA β and β-cell apoptosis, they are limited in that they were demonstrated in insulinoma cells and relied on utilization of BEL to discern the involvement of iPLA β. While BEL, at concentrations that do not impact cPLA β or sPLA β activities, is a recognized potent inhibitor of iPLA β, it has been reported to also have inhibitory effects on non-iPLA β enzymes (reviewed in ref. 9).

In the present study, we therefore used mice in which the rat insulin 1 promoter (RIP) was used to overexpress iPLA β specifically in the β-cells (RIP-iPLA β-Tg)18 and global iPLA β-null (iPLA β-KO) mice19 to more directly assess the role of iPLA β in β-cell apoptosis. Our findings reveal that altered expression of iPLA β impacts β-cell survival and also provide the first evidence for iPLA β-mediated regulation of autophagy in the β-cells.

Results

Genotyping. Breeding pairs obtained from Dr. John Turk (WUSM in St. Louis, MO) were used to generate RIP-iPLA β-transgenic (Tg), iPLA β-deficient (KO) and age-matched littermate wild-type (WT) colonies at UAB in Birmingham, AL, and their genotype was identified by PCR analyses, as detailed.18 The expected band sizes for WT and RIP-iPLA β-Tg are a single band at 450 bp and 200 bp, respectively. The expected band sizes for iPLA β+/− (WT), iPLA β−/− (Het) and iPLA β−/− (KO) are a single band at 1,400 bp, two bands at 1,400 bp and 400 bp, and a single band at 400 bp, respectively. As shown in Figure 1, our breeding protocol generated progeny that could be identified as WT or RIP-iPLA β-Tg and WT, Het, or iPLA β-KO mice.

Verification of RIP-iPLA β-Tg and iPLA β-KO models. To validate the genotyping results, iPLA β expression in the progeny was assessed by iPLA β message, activity, and protein expression analyses (Fig. 2). As seen in Figure 2A, iPLA β mRNA is greater in the Tg islets and undetected in the KO islets, relative to corresponding WT islets. Enzymatic assays (Fig. 2B) revealed nearly 30-fold increase in catalytic activity in the Tg islets and a 50% decrease in KO islets, as compared with corresponding WT islets. Addition of ATP increased activity similarly in the WT and Tg groups but not in the KO group, relative to activity measured in the absence of ATP (Fold increase +ATP/-ATP: WT-Tg, 2.5 ± 0.6; Tg 2.1 ± 0.03; WT-KO, 3 ± 1.7; KO, 1.1 ± 0.5). Because ATP stimulation of activity is characteristic of iPLA β, these findings suggest that the PLA activity in the WT and Tg groups is manifested by iPLA β and that the low (near background) level of activity measured in the KO group is not. Immunofluorescence analyses in islet sections (Fig. 2C) confirmed higher iPLA β expression in the Tg (Fig. 2C, left panels) and its absence in the KO (Fig. 2C, right panels) group, relative to WT groups. Further, the merging of iPLA β fluorescence with insulin-containing cells confirms that the iPLA β expression is localized within β-cells of pancreatic islets. Taken together, these findings confirm that iPLA β expression is increased in islet β-cells from the RIP-iPLA β-Tg-designated mice and is absent in the iPLA β-KO-designated mice, relative to their corresponding age-matched WT littermates, and that they can be used to study the impact of differential iPLA β expression in ER stress-induced apoptosis pathway in the β-cell.

Induction of ER stress-related factors. To assess susceptibility to ER stress, islets from WT, RIP-iPLA β-Tg, and iPLA β-KO mice were treated with thapsigargin for up to 48 h. Lysates were then prepared and resolved by SDS-PAGE to determine induction of ER stress factors CHOP, pPERK and GRP78. As seen in Figures 3A and B, all three factors increased within 24 h in the WT groups. In the RIP-iPLA β-Tg group, the increases were...
amplified at both 24 and 48 h, relative to the corresponding WT group. In contrast, while increased expression of the factors was evident in the iPLA-β-KO group, it was either similar (CHOP) or lower (GRP78) than that observed in the corresponding WT group. However, pPERK while similar at 24 h, was still expressed at 48 h in the KO but not in the WT. These findings suggest that the RIP-iPLA-β-Tg islets have greater susceptibility to developing ER stress than the iPLA-β-KO islets.

ER stress-induced activation of caspase-3. To further ascertain the impact of iPLA-β expression on β-cell apoptosis, cleavage (i.e., activation) of caspase-3 in islets was assessed in islets following treatment with thapsigargin. Immunoblotting analyses (Fig. 4A) revealed an increase in total caspase-3 in the WT and RIP-iPLA-β-Tg groups. In the Tg group, this was accompanied by an increase in cleaved caspase-3 (aC3) by 24 h. In contrast, total caspase-3 was unchanged and cleaved caspase-3 was undetectable in the KO group. Because immunoblotting was not sufficiently sensitive to reveal changes in cleaved caspase-3 in WT and KO groups, we performed two additional analyses. Immunofluorescence protocol allowed us to detect aC3 fluorescence in WT and KO islet sections but it was barely above background (Fig. 4B). In contrast, aC3 fluorescence was pronounced in the Tg islet and was found to be co-localized with insulin (I)-containing cells, as reflected by visualization of the merged yellow fluorescence. These findings suggest that ER stress promotes cleavage of caspase-3 and that this is amplified in RIP-iPLA-β-Tg islets and blunted in iPLA-β-deficient islets. Further evidence for this is provided in Figure 4C, which reveals amplified increase in aC3 activity in the RIP-iPLA-β-Tg islets, relative to WT and KO groups.

Basal neutral sphingomyelinase (NSMase). Earlier studies indicated that ceramides generated via NSMase-catalyzed hydrolysis of sphingomyelins was mediated by iPLA-β. We therefore hypothesized that islet NSMase expression is affected by iPLA-β expression levels. Total RNA was isolated and cDNA generated from islets from WT, RIP-iPLA-β-Tg and iPLA-β-KO mice and NSMase message expression was analyzed by qRT-PCR. As seen in Figure 5, NSMase mRNA was increased nearly 2-fold in the RIP-iPLA-β-Tg and significantly reduced in the iPLA-β-KO islets, relative to corresponding WT groups. These findings strengthen the notion that NSMase expression in pancreatic islets can be regulated by iPLA-β.

Ceramide and sphingomyelin analyses by mass spectrometry. To corroborate findings in Figure 5, ESI/MS/MS analyses were used to determine abundances of ceramide and sphingomyelin molecular species in islets, as previously described. To compare the different genotypes, the abundance of each species relative to internal standard was determined and normalized to total phosphate. As observed in insulinoma cells and human islets, the fatty amide substituents of the major ceramide species (Fig. 6A) endogenous to rodent islets were found to be 16:0 (m/z 544), 18:0 (m/z 572), 20:0 (m/z 600), 22:0 (m/z 628), 24:1 (m/z 654) and 24:0 (m/z 656), and the major sphingomyelin species (Fig. 6C) endogenous to islets were found to be 16:0 (m/z 709), 18:0 (m/z 737), 22:0 (m/z 693), 24:1 (m/z 819) and 24:0 (m/z 821). Comparison of basal ceramide (Fig. 6B) and sphingomyelin (Fig. 6D) pools in islets revealed similar abundance of both in the KO group, whereas ceramides were increased nearly 3-fold and sphingomyelins decreased ca. 40% in the RIP-iPLA-β-Tg group, relative to corresponding WT groups. Following exposure of WT islets to thapsigargin, the pool of ceramides increased (180 ± 12%) and of sphingomyelins decreased (12 ± 11%), relative to vehicle-treated WT group. Treatment of RIP-iPLA-β-Tg group caused a further increase in ceramides (245 ± 30%) and decrease in sphingomyelins (42 ± 5%), relative to the corresponding pools in WT treated islets. In contrast, in the KO treated group the pool of ceramides was 109 ± 17% and of sphingomyelins 88 ± 14%, relative to corresponding pools in WT treated islets. These findings are consistent with iPLA-β-mediated accumulation of ceramides, in part, via hydrolysis of sphingomyelins.
were 5-fold and 22-fold greater at 24 h and 48 h, respectively, in the RIP-iPLA\(_2\)β-Tg group. This reflected a nearly 5-fold higher incidence of apoptosis in the RIP-iPLA\(_2\)β-Tg, relative to corresponding WT group. Further, ER stress induced iPLA\(_2\)β protein in both the WT and RIP-iPLA\(_2\)β-Tg islets (Fig. 7B, inset), with the increase occurring in the RIP-iPLA\(_2\)β-Tg islets earlier than in the WT islets. In contrast, the fold increases were 3- and 11-fold greater at 24 and 48 h, respectively, in the iPLA\(_2\)β-KO group. Thus, while apoptosis was increased in the iPLA\(_2\)β-KO, relative to WT group, it was 50% lower than in the RIP-iPLA\(_2\)β-Tg group. These findings suggest that induction of ER stress in islets with thapsigargin promotes iPLA\(_2\)β expression and apoptosis and that these effects are amplified in RIP-iPLA\(_2\)β-Tg islets. In

**ER stress-induced islet cell apoptosis.** We next determined the impact of differential expression of iPLA\(_2\)β on ER stress-induced islet cell apoptosis. Following treatment of islets from WT, RIP-iPLA\(_2\)β-Tg and iPLA\(_2\)β-KO mice with thapsigargin, TUNEL analysis was used to visualize cells undergoing apoptosis. As seen in Figure 7A, vehicle treatment had minimal effect in all groups but TUNEL positivity increased in the islets following induction of ER stress. To facilitate quantitation of apoptotic cell number, the islets were dispersed and TUNEL fluorescence was quantitated by flow cytometry (Fig. 7B). Basal incidence of apoptosis was found to be similar among the groups. Following induction of ER stress, apoptosis was unchanged at 24 h but increased 3-fold at 48 h in both WT groups. In comparison, the fold increases were 5-fold and 22-fold greater at 24 h and 48 h, respectively, in the RIP-iPLA\(_2\)β-Tg group. This reflected a nearly 5-fold higher incidence of apoptosis in the RIP-iPLA\(_2\)β-Tg, relative to corresponding WT group. Further, ER stress induced iPLA\(_2\)β protein in both the WT and RIP-iPLA\(_2\)β-Tg islets (Fig. 7B, inset), with the increase occurring in the RIP-iPLA\(_2\)β-Tg islets earlier than in the WT islets. In contrast, the fold increases were 3- and 11-fold greater at 24 and 48 h, respectively, in the iPLA\(_2\)β-KO group. Thus, while apoptosis was increased in the iPLA\(_2\)β-KO, relative to WT group, it was 50% lower than in the RIP-iPLA\(_2\)β-Tg group. These findings suggest that induction of ER stress in islets with thapsigargin promotes iPLA\(_2\)β expression and apoptosis and that these effects are amplified in RIP-iPLA\(_2\)β-Tg islets. In
contrast, the islets deficient in iPLA$_{\beta}$ exhibit a reduced susceptibility to ER stress-induced apoptosis.

ER stress-induced loss in mitochondrial membrane potential (\(\Delta \Psi\)) in islet $\beta$-cells. Loss of $\Delta \Psi$ is a hallmark of cellular apoptosis and ceramides are reported to participate in this process.\textsuperscript{21,22} We therefore assessed $\Delta \Psi$ in WT, RIP-iPLA$_{\beta}$-Tg and iPLA$_{\beta}$-KO groups following vehicle (DMSO) or thapsigargin (T, 2 $\mu$M) for up to 48 h. Islet lysates were then prepared, resolved by SDS-PAGE, protein transferred to immunoblots and probed for ER stress factors. Immunoreactive bands were visualized by enhanced chemiluminescence. Each analysis was done a minimum of three times. (A) Immunoblotting analyses. Expression of CHOP, pPERK and GRP78 was determined using 30 $\mu$g protein aliquots. (B) Representative densitometry analyses. The ratios of the band intensity of protein of interest relative to loading control actin are presented (*significantly different from WT group, p < 0.05, n = 3/target).
β-cells, the islets were dispersed and FACS-purified to obtain a homogenous population of β-cells. The β-cells were then incubated with DiOC(6)$_3$, a fluorochrome that accumulates in the mitochondria of healthy cells but is not retained in the mitochondria of compromised cells. As evidenced in Figure 8, the green DiOC(6)$_3$ fluorescence is diminished in the WT
β-cells following thapsigargin treatment, reflecting ΔΨ loss in β-cell. In comparison, the loss in fluorescence is more dramatic in β-cells from the RIP-iPLA₂β-Tg, indicative of significant loss in ΔΨ in the RIP-iPLA₂β-Tg, relative to WT group. Interestingly, the mitochondrial-associated fluorescence was also reduced in β-cells from the iPLA₂β-KO, relative to corresponding WT group, suggesting that the loss of ΔΨ in the iPLA₂β-KO is greater than in the WT group. These findings suggest that iPLA₂β expression (up or down) can impact β-cell mitochondrial integrity.

Participation of iPLA₂β in β-cell autophagy. Autophagy is an ongoing pro-survival process but under increased stress, dysregulation of autophagy can lead to cell death. As an initial response to ER stress, autophagy is activated to increase cell survival, however, prolonged stress can activate apoptotic processes and cause cell death. To determine if an autophagic response to ER stress is influenced by iPLA₂β expression, autophagy was assessed in islets by monitoring conversion of LC3-II to LC3-I. Increased appearance of LC3-II is reflective of activation of the autophagic response in cells. As seen in Figure 9A and B, LC3-II is increased similarly in the WT groups. However, generation of LC3-II is markedly higher in the RIP-iPLA₂β-Tg, relative to corresponding WT group (Fig. 9A). In contrast, the generation of LC3-II is reduced in the iPLA₂β-KO, in comparison with corresponding WT group (Fig. 9B). This is reflected in the bar graphs, which illustrate higher LC3-II to loading control ratio in the RIP-iPLA₂β-Tg and reduced ratio in the iPLA₂β-KO, relative to corresponding WT groups.

To determine whether the ER stress-induced autophagosome (LC3-II) accumulation is due to autophagy induction or to inhibition of downstream steps, a turnover assay was utilized. This assay is based on the observation that LC3-II is delipidated in the lysosome and inhibition of lysosomal activity allows for assessment of induction of autophagy. The islets were treated with protease inhibitors (PIs) ammonium chloride, which prevents lysosomal acidification, and leupeptin, which prevents lysosomal hydrolase activities. Flux was then determined by comparing the ratio of LC3-II (normalized to loading control) between control and treatment conditions. The fold-change in the ratio is expected to remain unchanged when autophagy initiation is unaffected by the experimental condition, whereas, the fold-change will increase when initiation is enhanced or decreased when initiation is inhibited. We find that addition of the PIs caused a modest decrease (Fig. 9C) or no change (Fig. 9D) in induction of autophagy in the WT groups and that induction is not significantly altered in either the RIP-iPLA₂β-Tg (Fig. 9C) or iPLA₂β-KO (Fig. 9D) groups, as compared with corresponding WT group. Because ceramides are recognized to participate in autophagy, islets were treated with the NSMase inhibitor GW4869 and while induction of autophagy was not altered in the WT group, it was modestly reduced in the RIP-iPLA₂β-Tg group (Fig. 9C). These findings suggest that iPLA₂β participates in β-cell autophagy and raises the possibility that it impacts the autophagy process beyond the initiation step, in part, via activation of NSMase.

Discussion

Emerging evidence suggests β-cell apoptosis is a prominent contributor to β-cell death in T1DM and T2DM, making it important to understand the mechanisms underlying β-cell apoptosis if diabetes mellitus is to be prevented or delayed. Our studies with INS-1 cells, the Akita spontaneous ER stress model, and human pancreatic islet β-cells reveal that the Ca²⁺-independent phospholipase A₂β (iPLA₂β) participates in ER stress-induced β-cell apoptosis. These studies, however, are limited by several issues: (1) though insulinoma cell lines have contributed significantly to our understanding of β-cell biology, their functional properties are not identical to native pancreatic islet β-cells; (2) variability in human islet preparations, due to the nature of donor demise, isolation protocol at different procurement centers, and trauma related to shipment; and (3) reliance on BEL, a potent irreversible chemical inhibitor of iPLA₂β but also noted for its inhibition of non-iPLA₂β enzymes (reviewed in ref. 9), to discern the role of iPLA₂β in the apoptotic process. Though knockdown of iPLA₂β and NSMase in the insulinoma cells using siRNA protocols are supportive, they still leave open the question of whether iPLA₂β expression in islet β-cells impacts their survival.

We therefore set out to assess the role of iPLA₂β in ER stress-induced β-cell apoptosis by comparing responses in RIP-iPLA₂β-Tg and iPLA₂β-KO mouse islets. The RIP-iPLA₂β-Tg mouse is a particularly valuable model because iPLA₂β overexpression is restricted to only the islet β-cells. Our findings reveal that compared with the WT group, islet β-cells from RIP-iPLA₂β-Tg mice express higher iPLA₂β as expected, and exhibit increased susceptibility to outcomes due to thapsigargin-induced ER stress. In support of this, expression of ER stress factors (CHOP, GRP78 and pPERK) in the islets, and cleavage (i.e., activation) of caspase-3 and loss of membrane potential in the islet β-cells were all amplified in the RIP-iPLA₂β-Tg group, when compared with age-matched WT littermates. As a consequence, ER stress-induced apoptosis of the β-cells was...
have precluded further increases in ceramides and decreases in sphingomyelins. Alternatively, and a more likely possibility is that because the apoptotic process is amplified and occurs earlier in the RIP-iPLA2β-Tg islets, we were not able to capture the optimum time for analyses in the RIP-iPLA2β-Tg islets. Nevertheless, these findings suggest that increases in iPLA2β can lead to greater ceramide generation via sphingomyelin hydrolysis in islet β-cells.

It might be argued that if iPLA2β participates in the apoptosis process, a much more severe destruction of β-cell apoptosis should be evident under basal conditions as well. However, we did not find this to be the case as there were relatively small or no differences in outcomes (ER stress factors expression, mitochondrial membrane potential, activation of caspase-3, islet cell TUNEL positivity) measured in the WT and RIP-iPLA2β-Tg islets under basal conditions. The lack of basal changes in the presence of increased iPLA2β expression in β-cells is not entirely

Figure 6. Ceramide and sphingomyelin analyses by mass spectrometry. Islets were cultured O/N at 37°C under an atmosphere of 5% CO2/95% air and then prepared for ESI/MS/MS analyses. (A and C) Basal ceramide and sphingomyelin molecular species. Representative spectra obtained from WT mice illustrating molecular species of ceramides (A) and sphingomyelins (C) endogenous to islets. The labeled ions represent endogenous molecular species of ceramides and sphingomyelins. (B and D) Comparison of basal ceramide (CM) and sphingomyelin (SM) pools in RIP-iPLA2β-Tg and iPLA2β-KO islets. Abundance of each CM and SM molecular species, relative to internal standard was determined, normalized to total phosphate content, and the pool of ceramides and sphingomyelins in each group is presented as mean ± SEM (n = 3–5) (*significantly different from WT, p < 0.050).
unexpected because with the exception of increased insulin secretion, neither profound morphological nor functional changes in the islet were reported in the initial characterization if the RIP-iPLA₂-β-Tg model. As noted in another model in which islet β-cell protein expression is modified, the β-cell appears to be resistant under basal conditions and only when stressed is the impact of the modification unmasked.

We also report for the first time induction of iPLA₂ expression in a non-proliferative and native system (i.e., islet) during a biological process (i.e., ER stress). Intriguingly, iPLA₂ is also induced in the RIP-iPLA₂-β-Tg islet during ER stress. These findings raise the possibility that in the presence of a stress stimulus, not only are processes to increase iPLA₂ expression triggered, but that the potency of iPLA₂ becomes unmasked. This may occur via manifestation of higher specific catalytic activity due to caspase-3 catalyzed cleavage of iPLA₂ to a truncated and more active form or potential sequestration of iPLA₂ in organelles that are sensitive to the stimulus. The present findings also suggest the potential importance of the induced iPLA₂ in participating in the β-cell apoptotic process.

In contrast to the RIP-iPLA₂-β-Tg group, β-cells from the iPLA₂-KO mice are deficient in iPLA₂ but as observed in the RIP-iPLA₂-β-Tg group, no significant basal abnormalities in the measured parameters are evident. While all outcomes in response to ER stress are significantly attenuated in the iPLA₂-deficient group, relative to the RIP-iPLA₂-β-Tg group, they varied in comparison with their age-matched WT group. For instance, with respect to ER stress factors there is no difference in CHOP expression, GRP78 is reduced, and increased pPERK expression is maintained at 48 h: activation of caspase-3 and ceramide and sphingomyelin pools (basal and following thapsigargin treatment) are similar; and basal NSMase is reduced. In spite of the apparent lack of differences between WT and iPLA₂-KO in various parameters, incidence of β-cell apoptosis in the iPLA₂-KO, though significantly lower than in the RIP-iPLA₂-β-Tg group, was higher than in age-matched WT group. It must be recognized that ER stress alone can induce β-cell apoptosis and the increases in ER stress factors and caspase-3 cleavage in the iPLA₂-deficient are evidence of that.

A question that arises therefore is what promotes the higher incidence of apoptosis in the iPLA₂-deficient group. This is even more paradoxical in view of our earlier demonstrations that chemical inhibition or siRNA-mediated knockdown (KD) of iPLA₂ significantly attenuated insulinoma cell apoptosis. A salient difference between those and present studies is the duration of absence of an active iPLA₂ enzyme. Both BEL inhibition (30 min prior to thapsigargin exposure) and siRNA-KD (2 d before thapsigargin exposure) of iPLA₂ were acute protocols, in comparison with iPLA₂-deficiency for 3–4 mo in mice used in the present study. A potential explanation for the increased apoptosis in the iPLA₂-deficient group might be deduced from studies by Ma’s group. They reported that mitochondrial abnormalities and subsequent apoptosis promoted by staurosporine, which triggers the intrinsic mitochondrial apoptotic pathway, are prevented by expression of iPLA₂. They rationalized that this was due to availability of substrates normally provided by iPLA₂ to facilitate repair of membrane phospholipids, in particular cardiolipins, which are susceptible to damage by ROS-mediated peroxidation. In support of this possibility, they found evidence of increased sensitivity of islets from iPLA₂-deficient mice to staurosporine-induced mitochondrial abnormalities and apoptosis. Consistent with their findings, in the present study we observed that islet β-cells from iPLA₂-deficient mice exhibit...
Autophagy is a constitutively active process of cellular degradation. Understanding its role in β-cell dysfunction and survival has become increasingly important in the context of diabetes. In the present study, we explored the potential role of autophagy in the context of ER stress-induced β-cell dysfunction.

Using a combination of experimental approaches, we observed that ER stress triggers a reduction in autophagy, as evidenced by decreased LC3-II flux in islets deficient in iPLA₂. This reduction was associated with increased autophagic turnover and a more pronounced decrease in mitochondrial membrane potential. These findings suggest that autophagy may be a critical regulator of β-cell survival under stress conditions.

We further investigated the role of iPLA₂ in β-cell autophagy by comparing WT and iPLA₂-deficient islets. Our results showed that while iPLA₂ deficiency led to a decrease in autophagy, it also resulted in an increase in pro-apoptotic markers, indicating a potential role for autophagy in the regulation of β-cell apoptosis.

In conclusion, our study provides new insights into the complex interplay between autophagy and ER stress in β-cell dysfunction. It highlights the importance of autophagy in maintaining β-cell function and survival, and suggests that targeting autophagy might offer therapeutic opportunities in the treatment of diabetes.
translocate to the nucleus and induce expression of many gene products including that of PLA2G6, which encodes iPLA2β. The iPLA2β gene contains a sterol regulatory element, which can bind mSREBP to promote iPLA2β expression. Thus, we speculate that various stresses (ER, hyperglycemia, hyperlipidemia, oxidative, autoimmune responses) that are deleterious to the β-cell and associated with the evolution of diabetes potentially mediate their effects through activation of iPLA2β.

In this regard, elevated glucose and cytokine levels both activate iPLA2β in pancreatic islets. Continued studies will lead to a better understanding of the underlying cellular mechanisms governing the role of iPLA2β in islet β-cells and lead to identification of specific loci that can be targeted for drug therapy.

Figure 9. ER stress-induced autophagy in WT, RIP-iPLA2β-Tg and iPLA2β-KO islets. Islets (500/condition) from WT, RIP-iPLA2β-Tg and iPLA2β-KO mice were cultured O/N at 37°C under an atmosphere of 5% CO2/95% air and then treated with either vehicle Control (D, DMSO) or with thapsigargin (T, 2 μM) for 24 or 48 h. (A and B) ER stress-induced autophagy. (C and D) Autophagy induction due to ER stress. The islets were co-treated with thapsigargin and PIs (200 μM leupeptin and 20 mM ammonium chloride) to inhibit autolysosome activation. In some experiments the islets were pretreated with GW4869 (G, 20 μM) for 30 min prior to thapsigargin addition. Ratios of LC3-II to loading control actin in WT and RIP-iPLA2β-Tg islets (A and C) and in WT and iPLA2β-KO islets (B and D), and representative insets of LC3 immunoblots are presented (*significantly different from WT, p < 0.05, n = 3–4/group).

reported in T1DM. Further, gene expression analyses reveal increased expression of iPLA2β in peripheral blood mononuclear cells (PBMCs) from children with T1DM and interestingly, iPLA2β gene expression is induced in healthy PBMCs upon exposure to sera from recent diabetes patients. These observations are consistent with our hypothesis that increases in iPLA2β in the β-cells could contribute to β-cell dysfunction associated with diabetes.

In summary, our findings provide evidence for the involvement of iPLA2β in apoptosis and autophagy in β-cells due to ER stress. While our studies have focused on ER stress due to thapsigargin, to note is that many different stresses are associated with generation of mature (m) form of SREBP, which can
Materials and Methods

Materials. Mice (RIP-iPLAβ-Tg and iPLAβ-KO breeding pairs), generously provided by Dr. John Turk (Washington University School of Medicine), were bred and maintained, according to the IACUC policies at the University of Alabama at Birmingham (UAB). Other materials are as follows: Rabbit polyclonal antibody to LC3 from Abcam (ab51520); SYBR Green PCR Kit from Applied Biosystems (4385612); brain and egg sphingomyelins, ceramide and other lipid standards from Avanti Polar Lipids; rabbit monoclonal phospho-PERK and cleaved caspase-3 antibodies from Cell Signaling Technology Inc. (3179 and 9664); Accumax from Innovative Cell Technologies (AM105); AccuPrime Taq DNA polymerase system, SuperScript III first-strand synthesis system for PT-PCR, guinea pig anti-insulin, DiOC6(3), and Hoechst Stain from Invitrogen (12339-016, 18080-051, 18-0067, D273 and H21491, respectively); SDS-PAGE supplies and Triton X-100 from BioRad (161-0156 and 161-0407); normal goat serum, Cy3-conjugated affiniPure goat anti-rabbit IgG (H+L), and Dnk Anti-GP IgG-FITC from Jackson Immuno Research Laboratories (005-000-121, 111-165-003, and 706-096-148, respectively); Immobilon-P PVDF membrane from Millipore Corp. (IPVH00010); Slow Fade® light antifade kit from Molecular Probes (S2828); mouse monoclonal antibody to LC3 from Nano Tools Antikörpertechnik GmbH and Co. (0231S0203); L-α-1-palmitoyl-2-arachidonyl [1-14C] phosphatidylcholine (PAPC), 58 mCi/mmol from Perkin Elmer (NEC765); RNeasy kit from Qiagen Inc. (74106); TUNEL kit from Roche Diagnostic Corporation (1684795); CHOP, GRP78, actin, tubulin, bovine anti-goat IgG-HRP and goat anti-rabbit IgG-HRP from Santa Cruz Biotech Inc. (sc-575, sc-1050, sc-7210, sc-8035, sc-2350, sc-2030, respectively); caspase-3 colorimetric assay kit ammonium chloride, leupeptin, NSMase inhibitor GW4869, and protease inhibitor cocktail from Sigma Chemical Co. (CASP3C, A0171, L9783, D1692 and P8340, respectively); and SuperSignal® West femto chemi-luminescent substrate from Thermo Scientific (34094). All other common reagents and salts were obtained from Sigma Chemical Company.

Generation of RIP-iPLAβ-Tg and iPLAβKO mice and genotyping by PCR analyses. Breeders obtained from WUSM were used to generate colonies of WT, RIP-iPLAβ-Tg, and iPLAβKO mice at UAB. Tg founders (TG1 line) were mated with WT C57BL/6J mice (Jackson Laboratory) to generate RIP-iPLAβ-Tg mice and WT mice, and male and female iPLAβKO pairs were used to generate iPLAβKO (KO) and iPLAβKO (WT) mice, as previously described.18,17 Progeny genotype was determined using PCR analyses and the following sense/antisense primers: WT and RIP-iPLAβ-Tg - Set 1, CCT CCG GAG AGC AGC GAT TAA AAG TGT CA/TAG AGC TTT GCC ACA TCA CAG GTC ATT CAG and Set 2, CTA GGC TCA GAC ATC ATG CTG GAC GAG GT/AAG ATC TCA GTG TTT GTG AGC CAG GG were used together. Set 1 amplified the sequence in the internal control fatty acid-binding protein gene and the expected size of the product is 450 bp. Set 2 amplified the sequence that spans the junction of iPLAβ and globin cDNA in the TG construct and the expected size of the product is 200 bp. WT/ iPLAβKO—Set 1, AGC TTC AGG ATC TCA TGC CCA TC/CTC CGC TCC TCG GCC ATG GA (expected size of the product for WT is 1400 bp) and Set 2, GGG GCC TCA GAC TGG GAA GC/Neo: TCG CCT TCT ATC GCC TTC TTG AC (expected size of the product for KO is 400 bp) were used separately.

Islet isolation. Mice (3–4 mo age) were killed by cervical dislocation, abdomen exposed, and pancreata isolated. The common bile duct was clamped at the duodenum-bile duct junction, and collagenase/Kreb’s-Ringer buffer (5 ml) was injected into the pancreas via the duct. Once the pancreas was completely distended, it was removed and placed in a scintillation vial with collagenase/Kreb’s-Ringer buffer (2.5 ml) and incubated in a 37°C water bath for 15 min. The vial was then vigorously shaken for 90 sec, followed by washing (3×) of the pancreas with Krebs-Ringer buffer containing 1 mM CaCl2 (50 ml). The pancreas was then suspended in incomplete RPMI 1640 (without FBS or penicillin/streptomycin, 25 ml) and poured through a 70 μm cell strainer into a Petri dish. The cells were washed further with incomplete RPMI 1640 (75 ml). The cell strainer was then inverted and rinsed with complete RPMI 1640 (10% fetal bovine serum, 2× penicillin/streptomycin, 25 ml) to collect the remaining islets in solution. The islets were hand-picked under a microscope, counted, and incubated overnight in media under an atmosphere of 5% CO2/95% air and 37°C and then used for the experiments described below.

iPLAβ expression. To confirm that progeny islet expression of iPLAβ matched their genotype, total RNA was isolated from islets of each genotype using RNeasy kit (Qiagen Inc.). cDNA was then synthesized using SuperScript III kit (Invitrogen) for PCR analyses of iPLAβ message. PCR amplifications were performed using AccuPrime Taq DNA Polymerase System, and the sense/antisense primer sequences were cct gag cct cgt ggt tgg cct cag gtt and p8340, respectively; and SuperSignal® West femto chemi-luminescent substrate from Thermo Scientific (34094). All other common reagents and salts were obtained from Sigma Chemical Company.

Islet iPLAβ expression. To confirm that progeny islet expression of iPLAβ matched their genotype, total RNA was isolated from islets of each genotype using RNeasy kit (Qiagen Inc.). cDNA was then synthesized using SuperScript III kit (Invitrogen) for PCR analyses of iPLAβ message. PCR amplifications were performed using AccuPrime Taq DNA Polymerase System, and the sense/antisense primer sequences were cct gag cct cgt ggt tgg cct cag gtt and p8340, respectively; and SuperSignal® West femto chemi-luminescent substrate from Thermo Scientific (34094). All other common reagents and salts were obtained from Sigma Chemical Company.

Cytosol fraction was prepared from islets and protein concentration was determined using Coomassie reagent. Ca2+-independent PLA2 catalytic activity in an aliquot of cytosolic protein (30 μg) was assayed under zero Ca2+ conditions (no added Ca2+ plus 10 mm EGTA) in the presence of 16:0/[14C]20:4 GPC (PAPC, 5 μM) as the substrate, and specific enzymatic activity was quantitated, as described.23 Because stimulation of activity by ATP is a characteristic property of iPLAβ,21 the activity assay was also performed in the presence of 10 mM ATP.

Immunoblotting analyses. Islets were harvested at various times following induction of ER stress, sonicated, homogenates analyzed by SDS-PAGE (8 or 15%), and proteins transferred onto Immobilon-P PVDF membranes and processed for immunoblotting analyses. The targeted proteins and (1° antibody concentrations) were as follows: CHOP (1:500), GRP78 (1:500), iPLAβ (T14; 1:500), cleaved caspase-3 (1:1,000), LC3 (1:1,000), actin (1:500) and tubulin (1:1000). The secondary antibody concentration was 1:10,000. Immunoreactive bands were visualized by enhanced chemiluminescence.
In situ detection of DNA cleavage by TUNEL staining. Islets or dispersed islet cells were washed twice with ice-cold phosphate-buffered saline (PBS). Islets were then immobilized on slides by cytofpin and fixed at room temperature (RT) with 4% paraformaldehyde (in PBS, pH 7.4, 1 h). Dispersed cells were directly fixed with 4% paraformaldehyde for 20 min. The islets or dispersed cells were then washed with PBS and incubated in permeabilization solution (0.1% Triton-X-100 in 0.1% sodium citrate in phosphate-buffered saline, 30 min, RT). The permeabilization solution was then removed, TUNEL reaction mixture (50 μl) added, and the cells were incubated (1 h, 37°C) in a humidified chamber. The islets were washed again with PBS and counterstained with 1 μg/ml DAPI (4′,6-diamidino-2-phenylindole) in PBS for 10 min to identify cellular nuclei. Incidence of apoptosis was assessed under a fluorescence microscope using a FITC filter. Dispersed cells and flow cytometry were used to determine the percentage of apoptotic cells in islets.

Cleaved caspase-3 activity. To obtain a quantitative measure of apoptosis in isolated islets, cleaved (activated) caspase-3 (aC3) activity was assayed according to Manufacturer’s instructions. Islets were treated, harvested, resuspended in 1x lysis buffer (100 μl/200 islets, 20 min), sonicated and centrifuged at 18,000 g for 20 min at 4°C. The supernatants were then collected for the activity assay, which is based on measurement of aC3-catalyzed generation of p-nitroaniline (pNA) from Ac-DEVDD-pNA substrate. Ten μl of cell lysate or casp-3 positive control was incubated (3 h, 37°C, total volume of 1 ml) with 1 x assay buffer and the casp-3 substrate. The samples were then transferred to 1 ml quartz cuvettes and the absorbance of released pNA was read at 405 nm. Measured activity of cleaved caspase-3 was normalized to protein.

Immunostaining. Islets were fixed in 10% formalin and 5 μl of tissue marking dye, followed by the addition of 150 μl of low melting agarose. The mixture was spun down quickly to settle the islets at one surface of the agarose, which was then allowed to solidify. The islet-containing blocks were then processed, and paraffin sections (8–10 μm) were prepared for iPLA, αC3 and insulin staining. The sections were incubated overnight with primary antibodies (1:25), washed with PBS (4 x 30 min), incubated for 2–3 h with secondary antibodies (1:100 of Cy3 for insulin and Alexa Fluor 594 for iPLA, αC3 or cleaved caspase-3) and washed with PBS (3x, 10 min each). DAPI stain (20–30 μl) was then added, and the sections were sealed with a coverslip using nail polish. Fluorescence was recorded using a Nikon Eclipse TE300 microscope and images were captured at 20× magnification.

Quantitative RT-PCR. To determine mRNA expression of neutral sphingomyelinase (NSMase), total RNA was isolated from islets using RNeasy kit. cDNA was then synthesized using SuperScript III kit (Invitrogen) and heat-inactivated (70°C for 15 min). A reaction without reverse transcriptase was performed to verify the absence of genomic DNA. PCR amplifications were performed using SYBR Green PCR kit in an ABI 7000 detection system (Applied Biosystems). The sense/antisense primer sets for NSMase and 18S were ccg gat gca cac tac ttc aga a/gga ttg ggt gtc tgg aga agc and a/gt cct gcc ctt tgt aca ca/gat ccg agg gcc tca cta aac, respectively.

Ceramide analyses by electrospray ionization (ESI)/MS/MS. Lipids were extracted from islets under acidic conditions, as described. Briefly, islets were harvested, gently pelleted and extraction buffer (chloroform/methanol/2% acetic acid, 2/2/1.8; v/v/v) containing C8-ceramide (m/z 432) internal standard (IS, 500 ng), which is not an endogenous component of β-cell lipids, was added to the cellular pellet. After vigorous vortexing, the mixture was centrifuged (800 g) and the organic bottom layer was collected, concentrated to dryness under nitrogen and reconstituted in chloroform/methanol (1/4) containing 10 pmol/μl LiOH. To determine ceramide abundances, ESI/MS/MS standard curves were generated from a series of samples containing fixed amount of C8-ceramide standard and varied amounts of long-chain ceramide standards. The relative abundances of individual ceramide species, relative to the C8-ceramide IS, were measured by ESI/MS/MS scan for constant neutral loss of 48, which reflects the elimination of formaldehyde and water from the [M + Li+] ion. This loss is characteristic of ceramide-Li+ adducts upon low energy collisionally-activated dissociation ESI/MS/MS. Lipid phosphorous measurements were used to normalize individual ceramide molecular species.

Sphingomyelin (SM) analyses by ESI/MS/MS. Lipid extracts prepared as above were used for the sphingomyelin analysis. Sphingomyelins are formed by reaction of a ceramide with CDP-choline, and similar to GPC lipids, they contain a phosphocholine as the polar head group. This feature of sphingomyelins facilitates identification of sphingomyelin molecular species by constant neutral loss scanning of trimethylamine ([M + H]+ - N(CH_3)_3) or constant neutral loss of 59, as described. The prominent ions in the total ion current spectrum are those of the even mass PC molecular species, and these mask the odd mass sphingomyelin signals. Constant neutral loss of 59, however, facilitates emergence of signals for sphingomyelin species at odd m/z values, reflecting loss of nitrogen. Lipid extracts were prepared as above in the presence of a 14:0/14:0-GPC (m/z 684, 8 μg) IS, which is not an endogenous component of β-cell lipids, and analyzed by ESI/MS/MS. Sphingomyelins abundances in the samples was determined based on standard curves generated using commercially available brain and egg sphingomyelins with a known percentage of each fatty acid constituent and the internal standard as described. Lipid phosphorous measurements were used to normalize individual sphingomyelin molecular species.

Islet dispersion and cell sorting. Islets were collected and washed with PBS (2x) before being dispersed into single cells. Islets were resuspended in 1 ml of Accumax and incubated for 1 h at 37°C. Dispersed cells were then washed once and passed through a filter (35 μm pore size) to eliminate cell clumps. Sorting protocol was based on endogenous flavin adenine dinucleotide (FAD) auto-fluorescence in β-cells. High and low fluorescent cells were sorted on a fluorescence-activated cell sorter (FACS, BD Biosciences). The FAD content of the dispersed cells was analyzed at an excitation wavelength of 488 nm, and collected at 525 nm. The group of high autofluorescent cell population typically comprised 90–95% β-cells.
Assessment of mitochondrial membrane potential. β-cells obtained using the FACS protocol were washed with PBS (2×) at room temperature and then incubated with DiOC6(3) solution (175 nm) for 15 min under an atmosphere of 5% CO2/95% air (37°C). The Hoechst reagent (5 μg/mL) was then added to stain the nucleus. After 20 min, the cells were rinsed with PBS and mounted on slides, and then immediately examined using a confocal laser-scanning microscope (Zeiss) with a 488-nm argon laser and a 405-nm diode laser.

**Autophagy.** Islets (500 condition) were treated with vehicle (DMSO) or thapsigargin (2 μM) in the absence or presence of leupeptin (200 μM) and ammonium chloride (20 mM), which inhibit autolysosomal activity. In some experiments, islets were pre-treated with the NSMase inhibitor GW4869 (20 μM) for 30 min prior to addition of thapsigargin. Autophagy was monitored by determining the ratio of LC3-II to loading control.
