Abstract

Hyperosmotic stresses represent one of the major constraints that adversely affect plants growth, development, and productivity. In this study, the focus was on early responses to hyperosmotic stress- (NaCl and sorbitol) induced reactive oxygen species (ROS) generation, cytosolic Ca2+ concentration ([Ca2+]cyt) increase, ion fluxes, and mitochondrial potential variations, and on their links in pathways leading to programmed cell death (PCD). By using BY-2 tobacco cells, it was shown that both NaCl- and sorbitol-induced PCD seemed to be dependent on superoxide anion (O2•−) generation by NADPH-oxidase. In the case of NaCl, an early influx of sodium through non-selective cation channels participates in the development of PCD through mitochondrial dysfunction and NADPH-oxidase-dependent O2•− generation. This supports the hypothesis of different pathways in NaCl- and sorbitol-induced cell death. Surprisingly, other shared early responses, such as [Ca2+]cyt increase and singlet oxygen production, do not seem to be involved in PCD.

Key words: Calcium, hyperosmotic stress, mitochondria, NaCl, Nicotiana tabacum, non-selective cation channels, programmed cell death, reactive oxygen species.

Introduction

Salt stress is known to have severe effects on plant growth and development (Tester and Davenport, 2003). High salinity leads to ionic, osmotic, and oxidative stress in plants (Zhu, 2001) that may result in the induction of signalling events that lead to programmed cell death (PCD) in higher plants (Huh et al., 2002; Lin et al., 2006; Shabala, 2009; Wang et al., 2010) and algae (Affenzeller et al., 2009). Such PCD could be regarded as a salt adaptation mechanism (Huh et al., 2002). Drought, which consists at least in part of a hyperosmotic stress, was also shown to induce PCD in plants (Duan et al., 2010). PCD is an active cellular process that facilitates the removal of unwanted or damaged cells and is essential for cellular differentiation and tissue homeostasis (van Doorn et al., 2011). PCD has effectively been proved to occur in response...
to various abiotic stresses (Kadono et al., 2010; van Doorn et al., 2011). Different types of PCD with overlapping morphological and physiological hallmarks have been described in plants, which has led to a call for a detailed classification of cell death events (van Doorn, 2011; van Doorn et al., 2011). Although the delineation between the different PCD types of sometimes remains difficult (van Doorn et al., 2011), typical hallmarks of PCD in plants frequently include the fragmentation of the DNA by specific nucleases (DNA laddering), condensation and shrinkage of the cytoplasm, release of cytochrome c from mitochondria, elevation of the cytosolic calcium concentration ([Ca^{2+}]_{cyt}), generation of reactive oxygen species (ROS), and an activity increase of caspase-like enzymes (van Doorn, 2011; Tsiatsiani et al., 2011).

Although early events reported in responses to ionic and non-ionic hyperosmotic stress such as a transient [Ca^{2+}]_{cyt} increase (Xiong et al., 2002; Donaldson et al., 2004; Lin et al., 2006; Kim et al., 2007; Parre et al., 2007; Ranf et al., 2008), generation of ROS (Zhu, 2001; Xiong et al., 2002; Lin et al., 2006; Zhang et al. 2013), or up-regulation of protein kinases (Zhang et al., 2013) seemed to be shared in plants, some other responses are specific to one of these stresses. Under saline conditions, Na^{+} enters the cells through non-selective cation channels (NSCCs; Demidchik and Tester, 2002), depolarizing the plasma membrane (Chen et al., 2007; Hua et al., 2008; Shabala and Cuin, 2008; Pandolfi et al., 2010; Wegner et al., 2011). In contrast, isotonic mannitol or sorbitol solutions cause significant membrane hyperpolarization (Li and Delrot, 1987; Zingarelli et al., 1999; Shabala et al., 2000; Shabala and Lew, 2002). The DNA laddering, due to endonuclease release through permeable transition pores (PTPs) leading to mitochondria depolarization (Huh et al., 2002; Lin et al., 2006) occurred in NaCl-but not in sorbitol-stressed cells (Affenzeller et al., 2009). Thus, although some common events are induced upon osmotic stress, multiple signal transduction pathways are involved in the response to ionic and non-ionic hyperosmotic treatments (Donaldson et al., 2004; Parre et al., 2007).

In this study, it was shown using Bright Yellow 2 (BY-2) cells that both ionic and non-ionic hyperosmotic stresses effectively induced early singlet oxygen (O_2^{-}) generation and an O_2^{-}-dependent influx of Ca^{2+}, which are not involved in PCD processes. The PCD observed in response to NaCl and sorbitol seemed to be dependent on delayed superoxide anion (O_2^{-}) generation by NADPH-oxidase, this last being linked to Na^{+} influx through NSCCs and mitochondrial dysfunction only in the case of NaCl hyperosmotic stress.

### Materials and methods

**Cell culture conditions**

*Cotyledon tabacinum* L. BY-2 suspension cells were grown in Murashige and Skoog (MS) medium, pH 5.8 augmented with 30 g l^{-1} sucrose and 0.2 mg l^{-1} 2,4 D (Pauly et al., 2001). Cells were maintained at 22 ± 2 °C, under continuous darkness and continuous shaking (gyratory shaker) at 120rpm. Cell suspensions were subcultured weekly using a 1:15 dilution. All experiments were performed at 22 ± 2 °C using log-phase cells (6 d after subculture) maintained in their culture medium. Cell density was ~4 × 10^5 cells ml^{-1}.

**Osmolality changes**

The osmolality changes were systematically obtained by addition of 50 µl of sorbitol or NaCl from various stock solutions. For the measurement of extracellular medium osmolality changes after NaCl or sorbitol treatment, 100 µl of supernatant of cell suspensions treated with NaCl or sorbitol, were determined by the freezing depression method using an Automatic Micro-Osmometer Type 15 (Löser Messtechnik, Berlin, Germany).

**Cell viability assays**

Hyperosmosis-induced cell death in the cell suspension culture was determined by staining the dead cells with the vital dye Evans blue (0.005%, w/v) by mixing and incubating the cells and the dye for 1.2 h. Then stained cells were observed under a microscope. When appropriate, a 15 min pre-treatment with pharmacological effectors was done prior to NaCl or sorbitol exposure. Cells were counted under a microscope and cells that accumulated Evans blue were considered dead. At least 500 cells were counted for each independent treatment, and the procedure was repeated at least three times for each condition.

**Monitoring of ROS production**

The production of ROS was monitored by the chemiluminescence of the *Cypridina* luciferin analogue (CLA) as previously described (Kadono et al., 2006, 2010). CLA is known to react mainly with O_2^{-} and 1O_2 with light emission (Nakano, 1986), and allows measurement of extracellular ROS in plant cells (Tran et al., 2013). Chemiluminescence from CLA was monitored using an FB12-Berthold luminometer (with a signal integrating time of 0.2 s). For data analysis, the luminescence ratio (L/L_{basal}) was calculated by dividing the intensity of CLA luminescence (L) by the luminescence intensity before treatment (L_{basal}). The ROS scavengers 1,2-dihydroxybenzene-3,5-disulphonic acid disodium salt (Tiron), 1,4-diazabicyclo[2.2.2]octane (DABCO), and salicylhydroxamic acid (SHAM) were added 5 min before NaCl and sorbitol treatment. Other inhibitors were added to the cell suspension 30 min before NaCl and sorbitol treatment.

**Aequorin luminescence measurements**

The [Ca^{2+}]_{cyt} variations were recorded in a BY-2 cell suspension expressing the aequorin gene. Aequorin was reconstituted by overnight incubation in MS medium supplemented with 30 g l^{-1} sucrose and 2.5 µM native coelenterazine. Cell culture aliquots (500 µl) were transferred carefully into a luminometer tube, and the luminescence counts were recorded continuously at 0.2 s intervals with a luminometer. Treatments were performed by pipette injection of 50 µl of the effectors (NaCl or sorbitol). The residual aequorin was discharged by addition of 500 µl of a 1 M CaCl_2 solution dissolved in 100% methanol. The resulting luminescence was used to estimate the total amount of aequorin in each experiment. Calibration of calcium measurement was performed by using the equation: 

\[ pCa=0.32588(-\log_{10}k)+5.5953, \]

where k is a rate constant equal to luminescence counts per second divided by the total remaining counts (Knight et al., 1996). The results are expressed in micromolar Ca^{2+} and correspond to the mean±SD of 3–5 independent experiments.

**Voltage clamp measurements**

Experiments were conducted on 6-day-old cells maintained in their culture medium to limit stress (main ions in MS medium 28 mM NO_3^{-}, 16 mM K^+). Individual cells were immobilized by a microfunnel (~50–80 µm outer diameter) and controlled by a micromanipulator (WR6-1, Narishige, Japan). Impalements were carried out with a piezoelectric micromanipulator (PCS-5000, Burleigh Inst., USA) in
Six-day-old BY-2 suspension cells were collected and washed by filtration. Mitochondrial membrane potential measurement

The mitochondrial membrane potential was measured using the probe JC-1. The excitation wavelength was set at 514 nm, and the emission was detected at 530 ± 20 nm. The impact of NaCl and sorbitol additions on osmolality changes in BY-2 medium was first evaluated. It was found that the concentrations of NaCl (200 mM) and sorbitol (400 mM) most frequently used in this study showed almost the same osmolality shifts (Table 1). The shifts in osmolality induced by 400 mM sorbitol or 200 mM NaCl led to the death of a part of the cell population, dead cells displaying large cell shrinkage (Fig. 1A), the hallmark of the PCD process (van Doorn, 2011). Cell death scoring at various concentrations of sorbitol and NaCl showed the time- and dose-dependent progression of death (Fig. 1B, C), half of the cells being dead after 4 h at 400 mM sorbitol and 200 mM NaCl. In order to confirm whether this cell death was due to an active process requiring active gene expression and cellular metabolism, BY-2 cell suspensions were treated with actinomycin D (AD), an inhibitor of RNA synthesis, or with cycloheximide (Chx), an inhibitor of protein synthesis, each at 20 mg ml⁻¹, 15 min prior to 200 mM NaCl or 400 mM sorbitol exposure. In both cases, AD and Chx significantly reduced cell death (Fig. 1D). These results indicated that this cell death required active cell metabolism, namely gene transcription and de novo protein synthesis. Taken together, these data showed that saline or non-saline hyperosmotic stress induced a rapid PCD of a part of the N. tabacum BY-2 suspension cell population.

The kinetics of some early events classically detected upon saline stress or drought, namely an increase in cytosolic Ca²⁺, ion flux variations, ROS production, and mitochondrial membrane depolarization, were then followed, and it was checked how they could be involved in PCD induced by hyperosmotic stress.

Sorbitol- and NaCl-induced ROS generation

To study the effect of sorbitol on production of ROS in BY-2 cell suspension culture, the chemiluminescence of CLA, which indicates the generation of O₂⁻ and ^1O₂, was measured.

| Table 1. Osmolality changes in the medium after treatment with NaCl and sorbitol |
|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|
|                 |        |                 | 300             | 400             | 600             |
| Medium          | 100    | 200             | 200             | 400             | 600             |
| Osmolality (mosmol) | 182    | 369             | 558             | 944             | 375             | 606             | 952             |

Statistical analysis

Data were analysed by analysis of variance (ANOVA), and the mean separation was achieved by Newman and Keuls multiple range test. All numerical differences in the data were considered significantly different at the probability level of P ≤ 0.05.
used. Addition of 400 mM sorbitol to BY-2 cell suspension culture resulted in transient production of ROS that reaches the maximal level immediately after treatment (Fig. 2A). This sorbitol-induced ROS generation was dose dependent (Fig. 2B) and could be blocked using DABCO, an \( \cdot \mathrm{O}_2 \) scavenger, but not Tiron, an \( \cdot \mathrm{O}_2 \) scavenger (Fig. 2A, C). Addition of 200 mM NaCl to BY-2 cell suspension culture also resulted in transient production of ROS that reaches the maximal level immediately after NaCl treatment (Fig. 2D, E). In the case of sorbitol, only DABCO was able to decrease the NaCl-induced CLA chemiluminescence (Fig. 2D, F). Thus, in both cases the early increase in CLA chemiluminescence seemed to be dependent on \( \cdot \mathrm{O}_2 \) generation but not on \( \cdot \mathrm{O}_2 \) generation. SHAM, an inhibitor of peroxidase (POX) (Kawano et al., 1998; Hossain et al., 2013), which could be responsible for extracellular \( \cdot \mathrm{O}_2 \) generation (Kawano et al., 1998; Kanofsky, 2000; Guo et al., 2009), was thus used. Pretreatment of the BY-2 cell suspension culture with 5 mM SHAM only slightly reduced the increase in CLA chemiluminescence induced by 400 mM sorbitol (Fig. 2C) but significantly reduced that induced by 200 mM NaCl (Fig. 2F). This suggests the involvement of POX, at least in NaCl-induced \( \cdot \mathrm{O}_2 \) generation.

The impact of ROS pharmacology on NaCl- and sorbitol-induced PCD (Fig. 1) was further checked. DABCO, the \( \cdot \mathrm{O}_2 \) scavenger, failed to decrease sorbitol- (400 mM) and

---

**Fig. 1.** NaCl- and sorbitol-induced cell death in tobacco BY-2 cells. (A) Light micrographs of BY-2 cultured cells stained with Evans blue 2 h after incubation with 400 mM sorbitol (centre) or 200 mM NaCl (right) compared with control cells maintained in their medium (left). Arrows indicate the cell shrinkage. (B) Effect of incubation time and concentration of sorbitol or NaCl on the extent of cell death. (C) Effect of pre-treatment with actinomycin D (AD; 20 \( \mu \)g ml\(^{-1} \)) or cycloheximide (Chx; 20 \( \mu \)g ml\(^{-1} \)) on sorbitol- and NaCl-induced cell death. Each data point and error bar reflect the mean and SD, respectively, of at least three independent replicates. *Significantly different from controls, \( P < 0.05 \); **significantly different from the NaCl- or sorbitol-treated cells, \( P < 0.05 \). (This figure is available in colour at JXB online.)
NaCl- (200 mM) induced cell death and even increased NaCl-induced cell death after 2 h of treatment (Fig. 3A, B). For Tiron, the O$_2^-$ scavenger, there was no effect after 2 h but a decrease in cell death could be observed after 4 h treatment with NaCl (Fig. 3B). Thus, the hyperosmotic stress-induced cell death seemed not to be dependent on $^{1}$O$_2$ generation but on O$_2^-$ generation. Thus a possible delayed O$_2^-$ generation after treatment with 400 mM sorbitol or 200 mM NaCl was searched for. After such hyperosmotic stress, increases in CLA chemiluminescence could be detected (Fig. 3C). In both cases of CLA chemiluminescence increases, the maximum chemiluminescence levels were reached after 1 h and then decreased to the control level after 4 h, the decrease being more rapid upon NaCl treatment (Fig. 3C). It is noteworthy that these increases occurred before cell death reached the plateau level (Fig. 1B, C). These increases in CLA chemiluminescence could be inhibited by pre-treatment with Tiron, but also with 10 $\mu$M DPI, an inhibitor of NADPH-oxidase (Fig. 3D), suggesting that the generation O$_2^-$ through enhancement of NADPH-oxidase activity was involved in the delayed ROS generation after treatment with sorbitol and NaCl (Fig. 3C). In agreement with this, 10 $\mu$M DPI could also significantly reduce both sorbitol- and NaCl-induced cell death after 4 h (Fig. 3A, B).
Sorbitol and NaCl induce a rapid change in $[\text{Ca}^{2+}]_{\text{cyt}}$

The changes in $[\text{Ca}^{2+}]_{\text{cyt}}$ were monitored by the $\text{Ca}^{2+}$-dependent emission of blue light from aequorin (Knight et al., 1996). Treatment of BY-2 cells with sorbitol (400 mM) resulted in a rapid transient increase in aequorin luminescence (Fig. 4A) reflecting an increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ of $0.145 \pm 0.035 \mu\text{M} (n=23)$. This increase could be inhibited by the presence of $\text{Ca}^{2+}$ channel blockers, LaCl$_3$ and GdCl$_3$, when $\text{Ca}^{2+}$ internal store inhibitors (U73122 and dantrolene, Meimoun et al., 2009) showed no significant inhibitory effects (Fig. 4B), indicating that the sorbitol-induced increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ is mainly due to influx of $\text{Ca}^{2+}$ across the plasma membrane through $\text{Ca}^{2+}$ channels. As the generation of $^{1}\text{O}_2$ by sorbitol occurred immediately upon hyperosmotic stress (Fig. 2A), the effect of ROS pharmacology on the sorbitol-induced increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ was further tested. The $^{1}\text{O}_2$ scavenger DABCO strongly reduced the $[\text{Ca}^{2+}]_{\text{cyt}}$ increase compared with that in control cells; the POX inhibitor SHAM showed lower efficiency, while no differences were seen with the $^{1}\text{O}_2$ scavenger Tiron (Fig. 4A, C). These results strongly suggested that sorbitol-induced $\text{Ca}^{2+}$ uptake through $\text{Ca}^{2+}$ channels occurs downstream of the sorbitol-induced $^{1}\text{O}_2$ generation.

In the same way, treatment of BY-2 cells with NaCl (200 mM) resulted in a transient increase in aequorin luminescence (Fig. 4D), reflecting an increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ of $0.217 \pm 0.059 \mu\text{M} (n=23)$. As for sorbitol, inhibitors of $\text{Ca}^{2+}$ release from intracellular organelles (U73122 and dantrolene) failed to suppress the NaCl-induced increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ whereas $\text{Ca}^{2+}$ channel blockers LaCl$_3$ and GdCl$_3$ were efficient at reducing the NaCl-induced increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ (Fig. 4E). In a similar manner to what was observed for sorbitol, this increase was shown to be inhibited by the presence of DABCO (Fig. 4F) but less efficiently by SHAM, whereas Tiron seemed even to increase this $\text{Ca}^{2+}$ influx (Fig. 4D, F). The effect of the $\text{Ca}^{2+}$ channel inhibitor La$^{3+}$ on NaCl- and sorbitol-induced cell death in BY-2 suspension-cultured cells was then studied. Lanthanum (500 $\mu\text{M}$) failed to decrease sorbitol- (400 mM) and NaCl- (200 mM) induced cell death and even increases this cell death after 2 h of treatment (Fig. 4G), as observed for DABCO with NaCl (Fig. 3B). These data are in agreement with the link observed between the immediate $^{1}\text{O}_2$ generation inducing an influx of $\text{Ca}^{2+}$ upon sorbitol or NaCl stress and further suggest that these early induced events are not involved in a pathway leading to PCD.

Fig. 3. Effects of ROS scavengers on NaCl- or sorbitol-induced cell death in BY-2 cells. (A) Effect of Tiron, DABCO, or DPI, an NADPH-oxidase inhibitor, on cell death induced by 400 mM sorbitol after 2 h or 4 h treatment. (B) Effect of Tiron, DABCO, or DPI on cell death induced by 200 mM NaCl after 2 h or 4 h treatment. (C) Time course of CLA chemiluminescence during 6 h treatment with 400 mM sorbitol or 200 mM NaCl. (D) Inhibition of sorbitol and NaCl-induced delayed ROS generation by Tiron or DPI. Each data point and error bar reflect the mean and SD, respectively ($n=3$). *Significantly different from controls, $P<0.05$; **significantly different from the NaCl- or sorbitol-treated cells, $P<0.05$. 

In the same way, treatment of BY-2 cells with NaCl (200 mM) resulted in a transient increase in aequorin luminescence (Fig. 4D), reflecting an increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ of $0.217 \pm 0.059 \mu\text{M} (n=23)$. As for sorbitol, inhibitors of $\text{Ca}^{2+}$ release from intracellular organelles (U73122 and dantrolene) failed to suppress the NaCl-induced increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ whereas $\text{Ca}^{2+}$ channel blockers LaCl$_3$ and GdCl$_3$ were efficient at reducing the NaCl-induced increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ (Fig. 4E). In a similar manner to what was observed for sorbitol, this increase was shown to be inhibited by the presence of DABCO (Fig. 4F) but less efficiently by SHAM, whereas Tiron seemed even to increase this $\text{Ca}^{2+}$ influx (Fig. 4D, F). The effect of the $\text{Ca}^{2+}$ channel inhibitor La$^{3+}$ on NaCl- and sorbitol-induced cell death in BY-2 suspension-cultured cells was then studied. Lanthanum (500 $\mu\text{M}$) failed to decrease sorbitol- (400 mM) and NaCl- (200 mM) induced cell death and even increases this cell death after 2 h of treatment (Fig. 4G), as observed for DABCO with NaCl (Fig. 3B). These data are in agreement with the link observed between the immediate $^{1}\text{O}_2$ generation inducing an influx of $\text{Ca}^{2+}$ upon sorbitol or NaCl stress and further suggest that these early induced events are not involved in a pathway leading to PCD.
Fig. 4. Induction of $[\text{Ca}^{2+}]_{\text{cyt}}$ increase in aequorin-expressing tobacco BY-2 cells by sorbitol or NaCl. (A) Typical kinetics of sorbitol-induced increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ and modulation by ROS scavengers. (B) Modulation of sorbitol-induced $[\text{Ca}^{2+}]_{\text{cyt}}$ increase by the calcium channel blockers La$^{3+}$ or Gd$^{3+}$ (500 μM each) and the internal stock release inhibitors U73122 (100 μM) and dantrolene (10 μM). (C) Modulation of sorbitol-induced $[\text{Ca}^{2+}]_{\text{cyt}}$ increase by DABCO, a scavenger of singlet oxygen, Tiron, a scavenger of anion superoxide, or salicylhydroxamic acid (SHAM), an inhibitor of peroxidase. (D) Typical kinetics of the NaCl-induced increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ and modulation by ROS scavengers. (E) Modulation of the NaCl-induced $[\text{Ca}^{2+}]_{\text{cyt}}$ increase by La$^{3+}$, Gd$^{3+}$ (500 μM each), U73122 (100 μM), or dantrolene (10 μM). (F) Modulation of NaCl-induced $[\text{Ca}^{2+}]_{\text{cyt}}$ increase by DABCO, Tiron, or SHAM. (G) Effect of La$^{3+}$ on cell death induced by 200 mM NaCl (left) or 400 mM sorbitol (right) after 2 h or 4 h treatment. Each data point and error bar reflect the mean and SD, respectively ($n=5$). *Significantly different from controls, $P < 0.05$; **significantly different from the NaCl- or sorbitol-treated cells, $P < 0.05$.

Hyperosmotic constraints induce change in membrane potential and ion channel activities

Saline and non-saline hyperosmotic stresses are well known to modify the plasma membrane potential ($V_m$) of cells (Teodoro et al., 1998; Zingarelli et al., 1999; Shabala and Cuin, 2008; Wegner et al., 2011). By using an electrophysiological technique (dSEVC), the impact of NaCl and sorbitol on BY-2 cultured cell membrane potential was investigated. In control conditions in culture medium, the $V_m$ of BY-2 cells was $-21.1 \pm 2.2$ mV ($n=15$). In MS medium, the main ions are 16 mM K$^+$ and 28 mM NO$_3$–; thus the equilibrium potential estimated for K$^+$, $E_K$, is about –46 mV ([K]$_{out}=16$ mM with [K]$_{in}$ estimated at 100 mM). The equilibrium potential estimated for NO$_3$– is about –25 mV ([NO$_3$–]$_{out}=28$ mM with [NO$_3$–]$_{in}$ estimated at 5 mM). As previously observed with cultured cells of Arabidopsis thaliana (Kadono et al., 2010; Tran et al., 2013) or tobacco (Gauthier et al., 2007), the occurrence of anion currents in most of the BY-2 cells in their culture medium could explain the mean polarization of around –20 mV recorded in control and non-stressed conditions. The mean control value of these currents at –200 mV and after 1.8 s of voltage pulse was $-1.12 \pm 0.2$ nA ($n=11$). These currents were shown to be sensitive to structurally unrelated anion channel inhibitors, 9-anthracene carboxylic acid (9-AC) and glibenclamide (gli) (Supplementary Fig. S1 available at JXB online), reinforcing the hypothesis of an anionic nature for these currents. Addition of NaCl to suspension cultures resulted in a significant membrane depolarization (Fig. 5A) when sorbitol induced a hyperpolarization of the cells (Fig. 5A), clearly indicating a difference between saline and non-saline hyperosmotic stress. The sorbitol-induced hyperpolarization was correlated with a decrease in anion current (Fig. 5B) when the NaCl-induced depolarization was correlated with a large increase in whole-cell ion current (Fig. 5B). The positive shifts of the reversal potential of the current upon addition of NaCl are in accordance with a current carried by Na$^+$.

The influx of Na$^+$ through the plasma membrane by NSCCs was the most probable reason for the cell depolarization (Demidchick et al., 2002a, b), this Na$^+$ uptake was further checked using the Na$^+$-sensitive fluorescent probe Sodium Green (Wegner et al., 2011). An accumulation of fluorescence in the cytoplasm of the cells could be observed after

![Fig. 5.](https://academic.oup.com/jxb/article-abstract/65/5/1361/2884864)
1 h treatment with 200 mM NaCl (Fig. 6A). This fluorescence decrease could be reduced by using pre-treatments with inhibitors of NSCC, 5 mM tetracylammonium chloride (TEA+) or 1 mM quinine (Demidchick et al., 2002a) (Fig. 6A). Addition of 1 mM quinine or 5 mM TEA+ also allowed reduction of the NaCl-induced increase in currents (Fig. 6B, C) in BY-2 cells, as did verapamil (100 μM), another potent inhibitor of NSCCs (Demidchick et al., 2002a). The impact of these NSCC blockers on the extent of NaCl-induced cell death was thus further tested. The NSCC blockers were efficient at reducing the cell death induced by 200 mM NaCl (Fig. 6D), suggesting that NSCC activation is related to the NaCl-induced cell death. As this cell death was also dependent on a delayed ΔΨm generation by NADPH-oxidase (Fig. 3), the effect of the earliest activation of NSCCs by NaCl on this delayed ROS production was also checked. As for cell death, the NSCC blockers were efficient at reducing this NaCl-dependent delayed ROS production (Fig. 6E), suggesting that NaCl influx participates in the ΔΨm generation. Interestingly, the calcium channel blocker La3+ did not allow the delayed ROS generation to be decreased, confirming the hypothesis of the induction of different pathways in response to NaCl stress.

Mitochondrial depolarization is involved in NaCl- but not sorbitol-induced cell death

The role of mitochondria is well recognized in salinity tolerance (Jacoby et al., 2011), and dysfunction of mitochondria, leading to cytochrome c release upon salt stress, was shown to induce PCD in Thellungiella halophila suspension-cultured cells (Wang et al., 2010). Mitochondria are effectively pivotal in controlling cell life and PCD, through complex mechanisms that culminate in opening of PTPs leading to mitochondrial membrane potential (ΔΨm) loss (Vianello et al., 2007). It was thus checked whether NaCl and sorbitol lead to a decrease in ΔΨm in the present model. In untreated cells, the JC-1 fluorescence ratio of mitochondria displaying a high ΔΨm versus mitochondria presenting a low ΔΨm was greater than 1 (Fig. 7A). This ratio decreased in a time-dependent manner upon addition of NaCl (200 mM), indicating that NaCl induced a significant decrease of ΔΨm in some mitochondria when sorbitol (400 mM) induced an increase of ΔΨm during the first 30 min, the ratio reaching the control value after 2 h (Fig. 7A). Since a mitochondrial ΔΨm decrease during cell death was reported to be due to the formation of the mitochondrial PTPs (Vianello et al., 2007), the effect of cyclosporin A (CsA), an inhibitor of PTPs, was tested on NaCl-induced mitochondrial depolarization. A pre-treatment with CsA significantly reduced the NaCl-induced mitochondrial depolarization after 15 min (Fig. 7B), indicating that mitochondrial PTPs were involved in NaCl-induced mitochondrial depolarization. Moreover, pre-treatment with CsA significantly inhibited NaCl-induced cell death (Fig. 7C), indicating that PTP formation could participate in NaCl-induced cell death. As the activation of NSCCs occurs rapidly upon NaCl stress (Fig. 5A) and is involved in ROS generation (Fig. 6E), the impact of sodium influx on ΔΨm was investigated by using NSCC inhibitors. A significant reduction of NaCl-induced mitochondrial depolarization was observed after pre-treatment with verapamil (Fig. 7B). These data show that (i) two different pathways could be involved in the hyperosmotic stress-induced cell death; and (ii) the ROS generation dependent on Na+ influx could participate in the decrease in ΔΨm during NaCl-induced cell death.

Discussion

As expected from previous studies (Huh, 2002; Wang, 2010), the death of a part of the BY-2 cell population characterized by large cell shrinkage, a hallmark of the PCD process (van Doorn, 2011), was observed in response to NaCl-induced hyperosmotic stress. The extent of cell death was time and dose dependent, reaching about half of the population in 4 h with 200 mM NaCl. In order to check whether this cell death was due to an active mechanism requiring active gene expression and cellular metabolism, BY-2 cell suspensions were treated with AD, an inhibitor of RNA synthesis, or with Chx, an inhibitor of protein synthesis, prior to NaCl exposure. AD and Chx significantly reduced the NaCl-induced cell death. These results indicated that this cell death required active cell metabolism, namely gene transcription and de novo protein synthesis. The same behavior, namely time- and dose-dependent cell death characterized by cell shrinkage and requiring active metabolism using iso-osmotic concentrations of sorbitol, was observed here. This suggests that non-ionic hyperosmotic stress, like ionic hyperosmotic stress, could induce PCD in BY-2 cells as previously observed in various animal cell lines (Murata et al., 2002; Galvez et al., 2003; Niswander and Dokas, 2007). It was then checked whether some early events classically detected during hyperosmotic stress responses and PCD in plant could be involved in this cell death, namely ROS production, an increase in cytosolic Ca2+, ion flux variations, and mitochondrial membrane depolarization.

The earliest response observed after exposure of BY-2 cells to NaCl was an immediate peak of ROS. Addition of Tiron (a scavenger of O2−) did not significantly reduce NaCl-induced ROS generation, whereas DABCO (a scavenger of 1O2) avoided this production. Although 1O2 formation is likely to occur during the exposure to high light intensities (Krieger-Liszkay, 2004), it was also found that different enzymes including POXs could produce extracellular 1O2 in animals (Kanofsky, 2000; Stief, 2003; Tarr and Valenzeno, 2003) and in plant cells (Kawano et al., 1998; Guo et al., 2009). As the studied cultured cells were non-photosynthetic, the POX inhibitor SHAM was further tested (Kawano et al., 1998; Hossain et al., 2013), and this could reduce the early NaCl-induced ROS generation effectively. Thus, it would appear that these early transient 1O2 generations are not specific to ionic or non-ionic hyperosmotic stress.

In the case of both NaCl and sorbitol treatments, rapid transient [Ca2+]cyt increases in BY-2 cells were observed, as previously described in various models (Knight et al., 1997; Donaldson et al., 2004; Lin et al., 2006; Parre et al., 2007; Ranft et al., 2008). In BY-2 cells, these [Ca2+]cyt increases were inhibited by the calcium channel blockers La3+ and...
Fig. 6. (A) Confocal imaging of NaCl accumulation in BY-2 cells after 1 h treatment with 200 mM NaCl using the Sodium Green fluorescent probe (left). Decrease in fluorescence in cells pre-treated with quinine (1 mM) or TEA+ (5 mM), blockers of non-selective cation channels (NSCCs), prior to NaCl treatment (right). Corresponding bright field images are shown on the line below. Each image is representative of symptoms observed in at least three independent experiments. (B) Variations of whole-cell currents recorded before and after addition of 200 mM NaCl and subsequent addition of 1 mM quinine or 5 mM TEA+. The protocol was as illustrated; the holding potential (V_h) was V_m. (C) Mean values of whole-cell current variations (recorded at –200 mV and 1.8 s) after treatment with 200 mM NaCl with or without the NSCC blockers quinine (1 mM), TEA+ (5 mM), or verapamil (200 μM). Current variations are given as a percentage of the control level before treatments. The data correspond to means of at least five independent replicates, and error bars correspond to the SD. (D) Effect of pre-treatments with the NSCC blockers on NaCl-induced cell death. The data correspond to means of at least four independent replicates, and error bars correspond to the SD. (E) Effect of pre-treatments with the NSCC blockers or with La3+ (500 μM) on NaCl-induced delayed ROS generation and cell death. The data correspond to means of at least five independent replicates, and error bars correspond to the SD. *Significantly different from controls, P < 0.05; **significantly different from the NaCl- or sorbitol-treated cells, P < 0.05. (This figure is available in colour at JXB online.)
Gd³⁺ but not by dantrolene and U73122, inhibitors of calcium-induced calcium release channels and of the inositol triphosphate receptor, respectively, known to be efficient in plants (Meimoun et al., 2009). This suggests that the [Ca²⁺]cyt increase was not due to Ca²⁺ release from intracellular Ca²⁺ stores, but to an influx through plasma membrane-permeable Ca²⁺ channels. Although rapid, the Ca²⁺ influxes happened after the O₂ generation since DABCO pre-treatments strongly decreased these influxes, suggesting that they were dependent on the generation of O₂. Accordingly, SHAM decreased the Ca²⁺ influxes to a lower extent and Tiron was unable to decrease them. This confirms the hypothesis that an O₂-dependent Ca²⁺ influx was induced by sorbitol and NaCl and highlights the role of O₂ as a signalling molecule (Fischer et al., 2013).

Perturbation of Ca²⁺ homeostasis in plant cells, as well as in animal cells, has been described as a prerequisite for PCD (Grant et al., 2000; Davis and Distelhorst, 2006; Lecourieux et al., 2006). It was not possible to ascertain that in the BY-2 population all cells respond with a Ca²⁺ increase in the face of hyperosmotic stress. However, if only non-dying cells respond with a Ca²⁺ increase, this Ca²⁺ increase has no role in inducing PCD. In other words, if only dying cells (or even all cells) respond with a Ca²⁺ increase, since La³⁺ was inefficient in decreasing NaCl- and sorbitol-induced cell death, and even enhanced this cell death, it could suggest that Ca²⁺ influx could participate in cell protection. After perception of salt stress, the Ca²⁺ spike generated in the cytoplasm of root cells is known to activate the Salt Overly Sensitive (SOS) signal transduction cascade to protect the cells from damage due to excessive ion accumulation (Ji et al., 2013). SOS3 encodes a myristoylated calcium-binding protein that appears to function as a primary calcium sensor to perceive the increase in cytosolic Ca²⁺ triggered by Na⁺ excess that has entered the cytoplasm. Upon binding to Ca²⁺, SOS3 is able to interact with and activate the protein kinase SOS2 which phosphorylates SOS3 proteins. SOS3–SOS2 interactions recruit SOS2 to the plasma membrane, leading to activation of the downstream target SOS1, an Na⁺/H⁺ antiporter allowing extrusion of excessive Na⁺ from the cytosol (Ji et al., 2013). However, in

Fig. 7. (A) Variations of mitochondrial membrane potential (ΔΨm) of BY-2 tobacco cells after treatments with 200 mM NaCl or 400 mM sorbitol. (B) Effect of 50 μM cyclosporin A (CsA), an inhibitor of the permeability transition pore, 1 mM quinine, or 200 μM verapamil, inhibitors of NSCCs, on ΔΨm variation induced by 200 mM NaCl after 15 min. The data reflect the means±SE of at least four independent experiments. (C) Effect of 50 μM CsA, 1 mM quinine, or 200 μM verapamil on cell death induced by 200 mM NaCl. The data reflect the means±SE of at least three independent replicates. *Significantly different from controls, P < 0.05; **significantly different from the NaCl-treated cells, P < 0.05.
the present model, neither of these early linked events, Ca\(^{2+}\) increase and \(\cdot O_2\), seemed to be involved in PCD.

On the other hand, Tiron, a scavenger of \(\cdot O_2\), and DPI, an inhibitor of NADPH-oxidase, decreased the NaCl- and sorbitol-induced cell death and the delayed generation of ROS. This indicated that the delayed and more sustained \(\cdot O_2\) generation from NADPH-oxidase activity could play a central role in the death of these cells. Several reports implicate NADPH-oxidase activity in production of ROS in salinity stress, with the ROS resulting in Ca\(^{2+}\) influx. In the present model, no effect of DPI on early stress-induced Ca\(^{2+}\) increase could be detected (Supplementary Fig. S2 available at *JXB* online), in accordance with the delayed DPI-sensitive ROS generation. However, from the present data, a delayed increase in Ca\(^{2+}\) linked to NADPH-oxidase activity cannot be excluded, but this increase in Ca\(^{2+}\) should be La\(^{3+}\) independent, since La\(^{3+}\) could not decrease cell death. It is obvious that sorbitol-induced ROS generation could not depend on Na\(^{+}\) influx and thus possibly other hyperosmotic-induced events (e.g. NO production) could participate in NADPH-oxidase-dependent ROS generation observed in response to sorbitol and NaCl. However, upon NaCl stress, the delayed ROS generation could be decreased by quinine and verapamil, putative inhibitors of NSCCs (Demidchik *et al.*, 2002a, b). Even though no definitive molecular candidates have clearly emerged for NSCCs, it seems that various classes of NSCCs could be responsible for influx of Na\(^{+}\) under salt stress, especially a depolarization-activated class of NSCCs (Demidchik and Maathuis, 2007). A rapid and large depolarization of the BY-2 cells could be recorded upon NaCl addition due to an increase in a current sensitive to quinine and verapamil but also to TEA\(^{+}\), an inhibitor of K\(^{+}\) channels known to block some NSCCs (Demidchik *et al.*, 2002a). It could also be verified that the accumulation of Na\(^{+}\) in the cell was decreased upon pre-treatment with quinine or TEA\(^{+}\), strongly suggesting that NSCCs were responsible for Na\(^{+}\) influx into BY-2 cells. Moreover, these NSCC blockers were efficient in decreasing the NaCl-induced cell death, highlighting the toxic effect of Na\(^{+}\) as previously reported (Huh *et al.*, 2002; Affenzeller *et al.*, 2009; Wang *et al.*, 2010). It is further noticeable that La\(^{3+}\), a potent inhibitor of some NSCCs (Demidchick *et al.*, 2002a, b), was unable to decrease NaCl-induced cell death as well as the delayed ROS generation, whereas the NSCC blockers quinine, verapamil, and TEA\(^{+}\) failed to decrease the NaCl-induced Ca\(^{2+}\) increase (Supplementary Fig. S3 available at *JXB* online). This indicates that the Ca\(^{2+}\) influx was completely dissociated from Na\(^{+}\) influx through NSCCs. Moreover, sorbitol- and NaCl-induced Ca\(^{2+}\) influxes presented the same characteristics and were induced upon hyperpolarization in the case of sorbitol and depolarization in the case of NaCl, suggesting the voltage independence of the transporter involved. Further studies will be needed to determine if putative ligand-activated calcium channels such as cyclic nucleotide-gated channels or glutamate receptors could be responsible for these Ca\(^{2+}\) influxes in BY-2 cells; however, a putative candidate could be the calcium regulatory protein annexin (Laohavisit *et al.*, 2013).

Concerning ion flux regulation in response to sorbitol, a hyperpolarization of the BY-2 cells due to the decrease of anion currents was observed, as previously described in different models (Pennarun and Maillot, 1988; Teodoro *et al.*, 1998; Shabala *et al.*, 2000). Although such a regulation of anion current was shown to be involved during PCD induced by HrpN\(_{ea}\), a hypersensitive elicitor from *Erwinia amylovora* (Reboutier *et al.*, 2005), it did not seem to be involved in sorbitol-induced PCD since bromotetramisole, an activator of anion channels, failed to limit sorbitol-induced PCD (data

not shown), in contrast to the previously observed effect of HrpnNca (Reboutier et al., 2005).

Although ROS-activated outward-rectifying K+ channels (KORCs) were shown to be involved in salt-induced PCD (Demidchik et al., 2003, 2010), it was not possible to detect rapid activation of KORCs in response to NaCl or sorbitol. However, an activation of KORCs after addition of NaCl cannot be excluded, this current being masked in the large Na+ current recorded. On the other hand, KORC activation could also be delayed, as was recently reported in response to O3 (Tran et al., 2013).

Finally, one of the most important differences observed between sorbitol- and NaCl-induced PCD in BY-2 cells was the role of mitochondria. Sorbitol did not affect mitochondrial polarization and even slightly and transiently stimulated its polarization, whereas NaCl induced a large mitochondrial depolarization. This depolarization was probably involved in the formation of the PTP since CsA, an inhibitor of PTP, could reduce the NaCl-induced decrease in ΔΨm, as previously described (Wang et al., 2010) and also the NaCl-induced cell death. This could be related to observation made on Microceras denticulata (Affenzeller et al., 2009) for which a typical laddering of the DNA was only observed for NaCl-stressed cells but not for sorbitol-treated cells. The endonuclease responsible for this laddering could be released from mitochondria through PTPs (Vianello et al., 2007). It is to be noted that the inhibitors of NSCCs, verapamil, quinine, and TEA+, were also efficient in limiting the loss in ΔΨm, suggesting a direct role for cytosolic Na+-induced mitochondrial dysfunction.

As already described in numerous models, in BY-2 cells overlapping responses exist in response to ionic and non-ionic hyperosmotic stress and, among them, a PCD process. However, some overlapping responses such as the early transient \( ^3\text{O}_2 \) generation responsible for an influx of Ca\(^{2+} \) did not seem to be involved in PCD progress, while other shared responses such as the delayed NADPH-oxidase stimulation were important for these processes (Fig. 8). Specific responses also seemed to be involved in the PCD processes since upon NaCl stress, NADPH-oxidase stimulation was at least partly due to Na\(^+ \) influx through NSCCs, which also seemed to be responsible for mitochondrial depolarization not observed after the sorbitol challenge. Further studies will be needed to characterize fully the pathways leading to PCD induced by these hyperosmotic stresses.
