(Dated: September 5, 2018)

The crystalline electric field (CEF) of Ce$^{3+}$ in trigonal symmetry has recently become of some relevance, for instance, in the search of frustrated magnetic systems. Fortunately, it is one of the CEF case in which a manageable analytic solution can be obtained. Here, we present this solution for the general case, and use this result to determine the CEF scheme of the new compound CeIr$_3$Ge$_7$ with the help of $T$-dependent susceptibility and isothermal magnetization measurements. The resulting CEF parameters $B^+_2 = 34.4$ K, $B^+_4 = 0.82$ K and $B^+_4 = 67.3$ K correspond to an exceptional large CEF splittings of the first and second excited levels, 374 K and 1398 K, and a large mixing between the $|\pm \frac{5}{2}\rangle$ and the $|\mp \frac{3}{2}\rangle$ states. This indicates a very strong easy plane anisotropy with an unusual small $c$-axis moment. Using the same general expressions, we show that the properties of the recently reported system CeCd$_3$As$_3$ can also be described by a similar CEF scheme, providing a much simpler explanation for its magnetic properties than the initial proposal. Moreover, a similar strong easy plane anisotropy has also been reported for the two compounds CeAuSn and CePdAl$_4$Ge$_2$, indicating that the CEF scheme elaborated here for CeIr$_3$Ge$_7$ corresponds to an exemplary case for Ce$^{3+}$ in trigonal symmetry.

Keywords: Crystalline electric field, CeIr$_3$Ge$_7$.

INTRODUCTION

Cerium-based intermetallic compounds have been the subject of intensive research during the past decades. This is due to the variety of unconventional and remarkable properties that has been identified in this class of materials, as for instance heavy-fermion superconductivity [1, 2], multipolar order [3, 4], Kondo insulator ground state [5, 6] or non-Fermi-liquid behaviour associated with the density of states at the Fermi level (see, e.g., Ref. [11]). Depending on the CEF, Ce-based systems may also exhibit multipolar order: For instance, in the high-symmetry cubic structure the CEF yields to a quartet $\Gamma_8$ ground state which allows quadrupolar and AFM order like in Ce$_3$Pd$_{20}$Ge$_6$ [3, 15] or Ce$_{1-x}$La$_x$B$_6$ [16, 17].

In recent past years several Ce-based systems were studied with a trigonal symmetry for the Ce atoms, which is prone to frustration [10, 18, 22]. CeIr$_3$Ge$_7$ is one of these systems and is a prototypical example of case iii) [22]. Since the CEF has a very strong influence on the physical properties, especially in case iii), it is very important to determine the CEF scheme of a compound, i.e., the wave functions and the excitation energies of the different CEF levels. A standard approach is, e.g., to fit the anisotropy of the magnetic susceptibility over a wide $T$ range. For the general case, solving the CEF problem and calculating the magnetization implies solving a matrix of size $N \times N$, where $N$ is the degeneracy of the ground state $J$ multiplet: Thus, for Ce$^{3+}$, $N = 6$. However, in some cases in which the Ce site has a higher point symmetry, the problem can be highly simplified. A first simplification is to solve the CEF problem not at a finite magnetic field but at $B = 0$, and then to...
calculate the susceptibility using perturbation theory up to the second order. First and second order correspond to the Curie and the Van Vleck contributions, respectively. Because Ce\(^{3+}\) with an odd number of \(f\)-electrons is a Kramers system, the size of the relevant matrix is reduced to \(3 \times 3\). For some high symmetry cases, only one of the non-diagonal CEF parameters is allowed. As a consequence, only two of the \(|5/2, m_z\rangle\) states mix, while the third one remains a pure one. Accordingly, the \(3 \times 3\) matrix reduces to only one non-zero (diagonal) element and a \(2 \times 2\) block, which can easily be solved analytically. This is, e.g., the case for Ce\(^{3+}\) in a trigonal environment, for which simple analytical solutions are available in the literature [24]. Ce\(^{3+}\) in a trigonal environment is also such a case for which a manageable analytic solution can be obtained. However, because in the past the number of trigonal Ce-based systems was very limited, this analytical solution has not been published, yet. In the present paper we provide the general solution for the calculation of the CEF scheme and of the susceptibility of Ce in a trigonal environment. We use this general solution to analyze the anisotropic susceptibility of the two recently reported compounds CeIr\(_3\)Ge\(_7\) [23] and CeCd\(_3\)As\(_3\) [20]. In CeIr\(_3\)Ge\(_7\) we find an unusual large CEF splittings, with the second excited CEF level at about 1400 K. In CeCd\(_3\)As\(_3\) we show that its highly anisotropic susceptibility can be perfectly reproduced by the CEF scheme elaborated here using our general solution. This demonstrates that this compound is an easy plane system with a comparatively small exchange interaction and not an Ising system with a huge anisotropic exchange, as originally proposed in Ref. [20]. We compare the results for CeIr\(_3\)Ge\(_7\) and CeCd\(_3\)As\(_3\) with two further systems with trigonal symmetry, CeAuSn [18, 19] and CePdAl\(_4\)Ge\(_2\) [22], and show that this point symmetry generally results in a strong easy plane anisotropy and quite similar CEF schemes, making the CEF of CeIr\(_3\)Ge\(_7\) an exemplary case.

**EXPERIMENTAL TECHNIQUES**

For this work we have used single crystals (see Fig. 1) that were grown using self-flux technique [23]. X-ray diffraction was used for the identification of phase purity of the crystals and Laue method of back scattering reflection was used for the orientation. Using a superconducting quantum interference device (SQUID) and vibrating sample magnetometer (VSM), dc magnetic susceptibility and magnetization were measured between 1.8 and 600 K and in magnetic fields up to 7 T. A comprehensive study of transport, thermodynamic and magnetic properties of CeIr\(_3\)Ge\(_7\) is presented in Ref. [23].

**RESULTS**

CeIr\(_3\)Ge\(_7\) is one compound of a poorly studied RT\(_3\)M\(_7\) (R: rare earth, T: transition metal and M: XIV group element) family which crystallizes in the rhombohedral \(R\bar{3}c\) space group (isostuctural to ScRh\(_3\)Si\(_7\) [25]) with lattice parameters \(a = 7.89\,\text{Å}\) and \(c = 20.78\,\text{Å}\). The Ce atom has a single site at the \(6b\) position with trigonal point symmetry \(3\) (see Fig. 1). The structure is centrosymmetric.

This system is paramagnetic down to the AFM transition temperature of 0.63 K and presents a large magnetocrystalline anisotropy [23]. This is evidenced by the inverse magnetic susceptibility \(\chi^{-1} = B/M\) shown in Fig. 2 (left) between 1.8 and 600 K. The crystallographic \(c\)-axis is the magnetic hard axis. Above 400 K, \(\chi^{-1}\) follows a Curie-Weiss (CW) behaviour along both field directions. Fitting the data between 400 and 500 K, the CW law yields an effective moment \(\mu_{eff} = (2.52 \pm 0.1)\,\mu_B\), very close to that of the free Ce\(^{3+}\) ion of 2.54 \(\mu_B\). We fit only in this temperature range because of the slight upturn of \(\chi^{-1}\) for \(B \parallel [001]\) above 500 K, which is emphasized in Fig. 3 (right). This indicates an additional diamagnetic contribution \(\chi_0\) which is possibly due to the sample holder. This contribution was found to be \(\chi_0 = -2 \times 10^{-10}\,\text{m}^3/\text{mol}\). If subtracted, the high temperature CW fit yields an effective moment of 2.54 \(\mu_B\) as expected for a pure Ce\(^{3+}\) ion (cf. Fig. 3 left).

Since the point symmetry of the Ce atom is trigonal, the CEF Hamiltonian has just three parameters. Therefore, to solve exactly the CEF scheme it would be enough to fit the temperature dependence of the susceptibility and the field dependence of the magnetization at low temperature along both principal crystallographic axes. In fact, magnetization at 1.8 K (Fig. 2, right) suggests a saturation moment of about 1 \(\mu_B\) along [100] and much smaller along [001] for the ground state wave function. Before solving the Hamiltonian we can obtain an esti-
FIG. 2. Left: Inverse magnetic susceptibility of CeIr₃Ge₇ measured at \( B = 1 \) T applied along the [100] and [001] crystallographic axes. The grey lines are linear fits to Curie-Weiss law at temperatures between 400 and 500 K. Right: Field dependence of the magnetization measured at 1.8 K along the [100] and [001] axes.

mation of the CEF \( B_j^2 \) parameter by using the preliminary CW fits shown in Fig. 2: The paramagnetic Weiss temperatures along both principal crystallographic axes [100] and [001] are \( \theta_W^{[100]} = 9.5 \) K and \( \theta_W^{[001]} = -361 \) K, respectively. Since the ordering temperatures and thus exchange interactions in Ce-based systems are comparatively weak (\(< 10 \) K) because of the tiny de Gennes factor, the anisotropy of \( \chi(T) \) at high \( T \) is dominated by the effect of the crystalline electric field. The Weiss temperatures can be then expressed on the basis of a high-temperature series expansion as a function of the first CEF parameter \( B_j^0 \) [20], which is therefore a measure of the strength of the magnetocrystalline anisotropy:

\[
B_j^2 = (\theta_W^{[100]} - \theta_W^{[001]}) \frac{10k_B}{3(2J-1)(2J+3)}. \tag{1}
\]

Using the paramagnetic Weiss temperatures, we find that \( B_j^2 = 3.32 \) meV = 38.5 K. This value is consistent with the large difference between the saturation moments along the [100] and [001] directions observed in magnetization.

We can now use this value as a starting point for evaluating the CEF scheme. For the trigonal point symmetry of the Ce atoms in the crystal, the \( (2J+1) \) six-fold degenerate levels split into three Kramers doublets (see Fig. 3). The CEF Hamiltonian is given by

\[
H_{CEF} = B_2^0 O_2^0 + B_4^0 O_4^0 + B_4^3 O_4^3
\]

where \( B_m^n \) are CEF parameters and \( O_m^n \) are Steven operators [21,22] which are given by

\[
\begin{align*}
O_2^0 |J, m\rangle &= |3J_z^2 - J(J + 1)\rangle \\
O_4^0 |J, m\rangle &= |35J_z^4 - 30(J + 1)J_z^2 + 25J_z^2 - 6J(J + 1) + 3J^2(J + 1)^2\rangle \\
O_4^3 |J, m\rangle &= \frac{1}{4}[J_z(J_z^3 + J_z^1) + (J_z^3 + J_z^1)J_z]
\end{align*}
\]

with operators

\[
\begin{align*}
J_z |j, m\rangle &= m |j, m\rangle \\
J_x |j, m\rangle &= \frac{1}{2} (J_+ + J_-) |j, m\rangle \\
J_\pm |j, m\rangle &= [j(j + 1) - m(m \pm 1)]^{1/2} |j, m \pm 1\rangle
\end{align*}
\]

For the following calculations we define the [001] crystallographic direction as the quantisation axis \( z \) and the [100] direction as the \( x \) axis. Adding the Zeeman term, the global Hamiltonian is

\[
H_{CEF} = B_2^0 O_2^0 + B_4^0 O_4^0 + B_4^3 O_4^3 + g_J \mu_B B \tag{2}
\]

with \( g_J = 6/7 \) the Landé \( g \)-factor for Ce and \( \mu_B = 9.274 \times 10^{-21} \) J/T the Bohr magneton.

The CEF Hamiltonian matrix can be calculated by noting down all the non-zero matrix elements [23]. After rearranging the states we obtain

\[
\begin{array}{ccc}
\langle \pm \frac{3}{2} \rangle & |\frac{1}{2}\rangle & |\frac{1}{2}\rangle \\
\langle \frac{1}{2} \rangle & A & D & 0 \\
\langle \frac{3}{2} \rangle & D & B & 0 \\
\langle \frac{3}{2} \rangle & 0 & 0 & C
\end{array}
\]

where we have defined

\[
\begin{align*}
A &= (10B_2^0 + 60B_4^0) \\
B &= (-8B_2^0 + 120B_4^0) \\
C &= (-2B_2^0 - 180B_4^0) \\
D &= \pm (3\sqrt{10}B_4^1).
\end{align*}
\]

The solutions are three doublets of the form

\[
\begin{align*}
|\Gamma_{mix,1}\rangle &= \cos \alpha |\pm 5/2\rangle + \sin \alpha |\mp 1/2\rangle \\
|\Gamma_{mix,2}\rangle &= \sin \alpha |\pm 5/2\rangle - \cos \alpha |\mp 1/2\rangle \\
|\Gamma_{3/2}\rangle &= |\pm 3/2\rangle
\end{align*}
\]

with eigenvalues

\[
\begin{align*}
\epsilon_{mix} &= \frac{1}{2} \left[ (A + B) \pm \sqrt{(A - B)^2 + 4D^2} \right] \\
\Gamma_{mix} &= \sqrt{S_{mix}^2 + D^2} \\
\epsilon_{3/2} &= \langle \Gamma_{3/2}|H_{CEF}|\Gamma_{3/2}\rangle = C
\end{align*}
\]
The total susceptibilities are then given by:

\[ \chi^\text{total} = \chi^\text{para} + \chi^V, \quad \chi^\text{para} + \chi^V \]

These equations were used to fit the temperature depen-
and 150 K (with the intention to fit well the hump in the susceptibility of CeIr$_3$Ge$_7$ at low temperatures). The grey lines are linear fits to Curie-Weiss law which evidence a kink at about 10 K (left) possibly due to a small additional paramagnetic contribution and an upturn above 500 K due to a diamagnetic contribution from the sample holder.

Before fitting the data, it is useful to take a closer look at the inverse magnetic susceptibility $\chi^{-1}$ measured with $B \parallel [001]$ at low temperatures. This is because $\chi^{-1}$ along this direction is strongly temperature dependent and a fit to the data can already deliver correct CEF parameters. $\chi^{-1}$ vs. $T$ below 40 K is shown in the left panel of Fig. 4. $\chi^{-1}$ increases linearly with $T$ between 1.8 and 6 K with a slope of $1 \times 10^6$ mol/m$^3$K indicated by a grey line. This slope yields a CW effective moment of 0.8 $\mu_B$ and saturation moment of 0.46 $\mu_B$ which would be in agreement with the saturation magnetization expected from the field dependence of the magnetization measured at 1.8 K (cf. Fig. 1). However, at about 10 K we notice a significant change in slope into another linear increase with $0.5 \times 10^6$ mol/m$^3$K which extends to temperatures above 40 K. This would yield a saturation moment of 0.65 $\mu_B$ which seems to be much too high when compared with the measured magnetization at 1.8 K and with the value of $B_0^2$ extracted from the Weiss temperatures. A fit of $\chi^{-1}(T)$ for $B \parallel [100]$ at low $T$ gives a saturation moment of 1.1 $\mu_B$ which also agrees with the magnetization measured at 1.8 K. This implies that there is an additional paramagnetic contribution, possibly from a secondary phase, which affects the susceptibility along the hard axis at temperatures above 10 K. Above about 150 K its magnitude becomes negligible. For this reason, we fit our data along the [001] direction with equations (3) in the temperature ranges 1.8 - 6 K and 200 - 600 K. This procedure has been found to be correct, since a fitting of the susceptibility along the [001] direction between 10 and 150 K (with the intention to fit well the hump in $\chi^{-1}(T)$ in Fig. 2), would give a value of $B_0^2 < 30$ K which can not reproduce either the susceptibility results at high $T$ or the low-$T$ saturation magnetization. We also considered a possible misalignment of the sample and tried a fit with different weights for both crystallographic directions, but we were never able to reproduce the data correctly, since this change of slope at 10 K is too pronounced to be reproduced by a misalignment.

The fitted functions together with the experimental data are shown in Fig. 3 for both field directions. In our calculation the quantization z-axis is the experimental crystalline [001] direction. We could perfectly fit $\chi^{-1}(T)$ with $B \parallel [100]$ in the whole temperature range, the high-temperature part of $\chi^{-1}(T)$ with $B \parallel [001]$ as well as its low-$T$ part with a single set of CEF parameters. These parameters are listed in Tab. I. The $B_0^2 = 34.4$ K is a bit smaller that evaluated from Eq. 1 using the CW temperatures from fits shown in Fig. 5 which is 38.1 K. With the same set of parameters and the Zeeman energy in the Hamiltonian (Eq. 2) we calculated the magnetization at 1.8 K which is shown in the right panel of Fig. 5. The evolution of the magnetization in field does not correspond well to what has been measured, because we have not considered any exchange term in the Hamiltonian: Comparing the initial slope $M/B$ of the experimental data with that of the calculation we can provide an estimation of the exchange interaction which resulted to be 2.4 K, i.e., comparable with the Weiss temperature extracted from the Curie-Weiss fit of the average inverse susceptibility [23]. The saturation moments agree well with those measured by experiments. The small difference is due to other paramagnetic contributions as, e.g., from 5$d$ electrons. In fact, the CEF parameters leave $|\Gamma_{mix,1}|$ as the

![Graph of inverse magnetic susceptibility of CeIr$_3$Ge$_7$ at low (left) and high (right) temperatures.](image)

**TABLE I.** Crystalline electric field parameters for CeIr$_3$Ge$_7$ and CeCd$_3$As$_3$. We consider the reference level $E_0 = 0$ and $E_1 = \Delta_1$, $E_2 = \Delta_2$.

| CEF parameters | Energies | Mixing angle |
|----------------|----------|--------------|
| $B_0^2$ | $\Delta_1 = 374$ K | $\alpha = -57^\circ$ |
| $B_1^2$ | $\Delta_2 = 1398$ K | $\alpha = -57^\circ$ |
| $B_2^2$ | $\Delta_3 = 282$ K | $\alpha = -73.8^\circ$ |

For CeCd$_3$As$_3$ the ground state wave function with a mixing angle $\alpha = -57^\circ$ and energy splittings between the ground state and the first and second excited states of $\Delta_1 = 374$ K $\approx 32$ meV and $\Delta_2 = 1398$ K $\approx 120$ meV. These energy splittings are extremely large when compared with other Ce-based in-

b. First moment

$\chi_{\mu B} = g J \mu_B B$

$\chi_{\mu B} = g J \mu_B B$

$\chi_{\mu B} = g J \mu_B B$

FIG. 5. Left: Inverse magnetic susceptibility of CeIr$_3$Ge$_7$ measured at $B = 1$ T after subtraction of the diamagnetic $\chi_0$ contribution. The grey lines are linear fits to Curie-Weiss law between 400 and 600 K which yield an effective moment of 2.54 $\mu_B$, as expected for Ce$^{3+}$. The CW temperatures are $\theta_V^B = 5$ K and $\theta_V^B = -362$ K which give (from Eq. 1) $B_0^B = 38.1$ K. Right: Field dependence of the magnetization measured at 1.8 K. In both plots, the green lines are the results of the CEF calculations after having fitted $(\chi - \chi_0)^{-1}$ in the ranges 1.8 - 6 K and 200 - 600 K for $B \parallel [001]$ and in the whole measured range for $B \parallel [100]$.

these data with our model and found a very good agreement: The CEF parameters are listed in Tab. II and leave $|\Gamma_{mix,1}|$ as the ground state wave function with a mixing angle $\alpha = -73.8^\circ$ and energy splittings between the ground state and the first and second excited states of $\Delta_1 = 241$ K $\approx 20.8$ meV and $\Delta_2 = 282$ K $\approx 24.3$ meV. The saturation magnetizations parallel and perpendicular to the c-axis are $M_{B\parallel c} = 0.23 \mu_B$ and $M_{B\perp c} = 1.19 \mu_B$. Thus, our analysis shows that the strongly anisotropic susceptibility of CeCd$_3$As$_3$ and its peculiar $T$ dependence of the c-axis susceptibility can be fully accounted for by the CEF, with a CEF scheme quite similar to that of CeIr$_3$Ge$_7$, except for a smaller overall splitting. Therefore, instead of being a strongly Ising type system, CeCd$_3$As$_3$ is an easy plane XY system with a standard strength of the exchange interaction along both directions. This case demonstrate the importance of doing a CEF analysis before discussing the properties of a rare-earth-based magnetic system, and the value of a general analytical solution to the CEF problem.

In the course of our study we noticed two further systems with Ce$^{3+}$ in a trigonal (local) environment, CeAuSn [18] [19] and CePdAl$_2$Ge$_2$ [22]. Both show an anisotropy very similar to that of CeIr$_3$Ge$_7$, with a large easy plane susceptibility and a small c-axis CEF ground state moment. The CEF of CeAuSn has been well-analyzed in two successive papers [18] [19] leading to a convergent solution quite similar to that of CeIr$_3$Ge$_7$, except for a much smaller overall splitting. In contrast, for CePdAl$_2$Ge$_2$ no CEF analysis was performed, but the similarity of its susceptibility data to those of CeCd$_3$As$_3$ implies a very similar CEF scheme, too. Thus, all the trigonal Ce-based systems investigated recently bear a very similar CEF scheme with a very pronounced easy

To show the validity and the general character of our calculation we apply the same procedure to the recently discovered system CeCd$_3$As$_3$ [20]. The huge anisotropy of the susceptibility of this compound, as well as the weak $T$ dependence of its c-axis susceptibility led the authors of Ref. 20 to propose that CeCd$_3$As$_3$ is a very strong Ising type system with a huge anisotropy of the exchange interaction; the exchange along c being orders of magnitude larger than in the basal plane. However, these authors did not try to analyse their data using a CEF model. Susceptibility and magnetization data taken from Ref. [20] are plotted in Fig. 6.
plane anisotropy and a small c-axis CEF ground state moment. This origins from a large positive $B_2^0$ coefficient, but also from a large mixing coefficient $B_4^5$, which is of the same order or even larger than $B_2^0$, resulting in a large mixing between the $|\pm 1/2\rangle$ and the $|\pm 5/2\rangle$ states. This is a fundamental difference to purely hexagonal systems with a sixfold point symmetry, where the mixing term is absent, resulting in pure $|\pm 1/2\rangle$, $|\pm 3/2\rangle$ and $|\pm 5/2\rangle$ CEF doublets.

**DISCUSSION AND CONCLUSION**

A comprehensive analysis of the CEF scheme of Ce$^{3+}$ in the trigonal point symmetry has been presented. We provided a general analytic solution which can be used to solve the CEF problem and to calculate the anisotropic magnetic susceptibility for Ce in a trigonal surrounding. We have successfully used this solution to analyze the susceptibility of the new compound CeIr$_3$Ge$_7$ and to determine its CEF scheme. This analysis indicates that the ground state doublet in this compound is composed by a large mixing of the $|\pm 5/2\rangle$ and the $|\pm 1/2\rangle m_z$ states, and the first and second excited states are at 374 K and 1398 K, respectively. The latter value is exceptionally large compared to the typical values of 200 – 600 K observed in intermetallic Ce-based compounds. Further on, we used the same analytical solution to analyze the anisotropic susceptibility of CeCd$_3$As$_3$. We showed that the anisotropic susceptibility of this compound can be fully accounted for by the CEF, providing a much simpler and standard explanation for its peculiar susceptibility than that originally proposed. We found that two further compounds, CeAuSn and CePdAl$_4$Ge$_2$, presents a very similar anisotropy and accordingly a very similar CEF scheme to that of CeIr$_3$Ge$_7$. This indicates that the CEF of CeIr$_3$Ge$_7$ is an exemplary case for Ce-based systems with trigonal symmetry. This systematic study also shows that in intermetallic Ce-based systems a trigonal environment usually results not only in a large $B_2^0$ CEF parameter, but also to a large $B_4^5$ mixing CEF parameter, both leading to a pronounced easy plane behavior.

Our analysis indicates an unusual large overall CEF splitting in CeIr$_3$Ge$_7$. This huge splittings might be connected with the presence of 5$d$ ligands, i.e., nearest-neighbor iridium atoms (see Fig. 1). To check this idea, we have performed band structure calculations using the full-potential local-orbital FPLO code [32]. For the exchange and correlation potential, the local density approximation [33] was applied. The calculations were carried out scalar relativistically on a well converged $k$-mesh (20×20×20). The influence of the spin-orbit coupling to the valence states is rather small. We have used the room-temperature data of Ref. [23] for the lattice parameters and treated the cerium 4$f$-states as core states (open core approximation).

![FIG. 7. Calculated total and partial density of states (DOS) of CeIr$_3$Ge$_7$. Both Ir (red) and Ge(1) (blue) contribute almost equally to the DOS at the Fermi level. The inset shows the comparison to the fictitious isostructural Rh system (orange).](image)

The calculated density of states (DOS) is shown in Fig. 7. The valence band is essentially formed by strongly hybridized Ir (mostly Ir 5$d$) and Ge (mostly Ge 4$p$) states. A comparison between calculations of CeIr$_3$Ge$_7$ and the fictitious CeRh$_3$Ge$_7$ (we used the same lattice parameters and Wyckoff positions due to the very small difference in atomic size between Ir and Rh) shows that for the Ir-based system the band width, which is a measure of the hybridization, is significantly larger than in the Rh-based compound, indicating that the 5$d$ ligands create a substantially larger crystalline field. However, the precise estimation of the CEF parameters with density functional theory calculations is very complex and, most importantly, it depends strongly on the hybridization parameter $\Delta$ which is not known for CeIr$_3$Ge$_7$. The stronger $\Delta$ the larger the crystalline field [33]. A more quantitative description why this field is so large in CeIr$_3$Ge$_7$ can not be answered here and is beyond the scope of this paper.

**ACKNOWLEDGMENTS**

We are indebted to M. O. Ajeesh, R. Cardoso, D.-J. Jang and J. Sereni for useful discussions, and D. A. Sokolov for having oriented the crystal. APPENDIX

List of matrix elements

We list here all matrix elements for the calculation of the susceptibility.

Matrix elements for the paramagnetic susceptibility

For the field parallel to z-axis:

\[
\langle J_z \rangle:
\langle \Gamma_{3/2}(a) | J_z | \Gamma_{3/2}(a) \rangle = \frac{3}{2}
\langle \Gamma_{3/2}(b) | J_z | \Gamma_{3/2}(b) \rangle = -\frac{3}{2}
\]

Matrix elements for the Van Vleck susceptibility

Here, we assumed the reference level, \( E_0 = 0, E_1 = \Delta_1, E_2 = \Delta_2 \). Also we notice that

\[
\langle \Gamma_{mix,1} | J_\alpha | \Gamma_{mix,1} \rangle^2 = \langle \Gamma_{3/2} | J_\alpha | \Gamma_{3/2} \rangle^2
\]

Each of these elements has 4 different combinations of mixed states (a) and (b), evaluated each of them with the operators along both field directions, parallel to the z axis and perpendicular to it. For field parallel to the z-axis (\( J_z \)):

\[
\langle J_z \rangle:
\langle \Gamma_{mix,1} | J_z | \Gamma_{mix,1} \rangle = \langle \Gamma_{mix,1} | J_z | \Gamma_{mix,1} \rangle = 0
\]

For field perpendicular to the z-axis: \( \langle J_x \rangle, \langle J_y \rangle, \langle J_z \rangle \); Eigenfunctions of these operators are linear combinations of \( \langle \Gamma_{mix,1}(a) \rangle \) and \( \langle \Gamma_{mix,1}(b) \rangle \), \( \langle \Gamma_{3/2}(a) \rangle \) and \( \langle \Gamma_{3/2}(b) \rangle \), \( \langle \Gamma_{mix,2}(a) \rangle \) and \( \langle \Gamma_{mix,2}(b) \rangle \) and vice versa.

\[
\langle J_x \rangle:
\langle \Gamma_{mix,1}(a) | J_x | \Gamma_{mix,1}(a) \rangle = \frac{1}{\sqrt{2}} \langle \Gamma_{mix,1}(a) | J_x | \Gamma_{mix,1}(b) \rangle
\]

\[
\langle \Gamma_{mix,1}(d) | J_x | \Gamma_{mix,1}(d) \rangle = -\frac{3}{2} \sin^2 \alpha
\]

\[
\langle \Gamma_{mix,1}(c) | J_x | \Gamma_{mix,1}(c) \rangle = +3 \sin^2 \alpha
\]

\[
\langle \Gamma_{mix,1}(d) | J_x | \Gamma_{mix,1}(d) \rangle = -3 \sin^2 \alpha
\]
\[
\begin{align*}
    \langle \Gamma_{3/2} | J_z | \Gamma_{mix, 2} \rangle : \\
    \langle \Gamma_{3/2}(a) | J_z | \Gamma_{mix, 2}(a) \rangle &= \langle \Gamma_{mix, 2}(a) | J_z | \Gamma_{3/2}(a) \rangle = 0 \\
    \langle \Gamma_{3/2}(a) | J_z | \Gamma_{mix, 2}(b) \rangle &= \langle \Gamma_{mix, 2}(b) | J_z | \Gamma_{3/2}(a) \rangle = 0 \\
    \langle \Gamma_{3/2}(b) | J_z | \Gamma_{mix, 2}(a) \rangle &= \langle \Gamma_{mix, 2}(a) | J_z | \Gamma_{3/2}(b) \rangle = 0 \\
    \langle \Gamma_{3/2}(b) | J_z | \Gamma_{mix, 2}(b) \rangle &= \langle \Gamma_{mix, 2}(b) | J_z | \Gamma_{3/2}(b) \rangle = 0
\end{align*}
\]

For field perpendicular to the z-axis:

\[
\begin{align*}
    \langle \Gamma_{mix, 1} | J_z | \Gamma_{3/2} \rangle : \\
    \langle \Gamma_{mix, 1}(a) | J_z | \Gamma_{3/2}(a) \rangle &= +\frac{\sqrt{5}}{2} \cos \alpha \\
    \langle \Gamma_{3/2}(a) | J_z | \Gamma_{mix, 1}(a) \rangle &= +\frac{\sqrt{5}}{2} \cos \alpha \\
    \langle \Gamma_{mix, 1}(a) | J_z | \Gamma_{3/2}(b) \rangle &= +\sqrt{2} \sin \alpha \\
    \langle \Gamma_{3/2}(b) | J_z | \Gamma_{mix, 1}(a) \rangle &= +\sqrt{2} \sin \alpha \\
    \langle \Gamma_{mix, 1}(b) | J_z | \Gamma_{3/2}(a) \rangle &= +\sqrt{2} \sin \alpha \\
    \langle \Gamma_{3/2}(a) | J_z | \Gamma_{mix, 1}(b) \rangle &= +\sqrt{2} \sin \alpha \\
    \langle \Gamma_{mix, 1}(b) | J_z | \Gamma_{3/2}(b) \rangle &= +\frac{\sqrt{5}}{2} \cos \alpha \\
    \langle \Gamma_{3/2}(b) | J_z | \Gamma_{mix, 1}(b) \rangle &= +\frac{\sqrt{5}}{2} \cos \alpha
\end{align*}
\]
