Owing to the increasing prevalence of type 2 diabetes, the development of novel hypoglycemic drugs has become a research hotspot, with the ultimate goal of developing therapeutic drugs that stimulate glucose-induced insulin secretion without inducing hypoglycemia. Vasoactive intestinal peptide (VIP), a 28-amino-acid peptide, can stimulate glucose-dependent insulin secretion, particularly by binding to VPAC2 receptors. VIP also promotes islet β-cell proliferation through the forkhead box M1 pathway, but the specific molecular mechanism remains to be studied. The clinical application of VIP is limited because of its short half-life and wide distribution in the human body. Based on the binding properties of VIP and VPAC2 receptors, VPAC2-selective agonists have been developed to serve as novel hypoglycemic drugs. This review summarizes the physiological significance of VIP in glucose homeostasis and the potential therapeutic value of VPAC2-selective agonists in type 2 diabetes.

KEYWORDS
vasoactive intestinal peptide, VPAC2, insulin secretion, glucose-dependence, VPAC2-selective agonists

Abbreviations: AC, adenylate cyclase; ACh, acetylcholine; cAMP, cyclic adenosine monophosphate; Ccn4, cyclin A; Cdk1, cyclin-dependent kinase 1; CS-SeNPs, chitosan-modified SeNPs; ERK, extracellular-signal regulated kinase; FoxM1, forkhead box M1; GLP-1, glucagon-like peptide-1; GLUT4, glucose transporter 4; GPCR, G-protein-coupled receptor; IRS-1, insulin receptor substrate 1; PAC1, PACAP receptor type 1; PACAP, pituitary adenylate cyclase activating polypeptide; PEG, polyethylene glycol; PKA, protein kinase A; Plk1, polo-like kinase 1; SeNPs, selenium nanoparticles; SPIONs, superparamagnetic iron oxide nanoparticles; VIP, vasoactive intestinal peptide; VPAC1, VIP/PACAP receptor type 1; VPAC2, VIP/PACAP receptor type 2.
Introduction

Diabetes is a chronic disease with multiple etiology and a complicated pathogenesis, with a global prevalence that is currently increasing annually. According to the statistics released by the International Diabetic Federation in 2021, 537 million people suffer from diabetes worldwide, with an estimated global prevalence of 10.5%. The number of cases is expected to reach 783 million in 2045, with the prevalence rising to 12.2% (1). Of this, 90% are patients with type 2 diabetes (2). Type 2 diabetes is a metabolic disease characterized by chronic hyperglycemia and insulin resistance. Chronic hyperglycemia leads to glucose toxicity to vital organs, including the eyes, kidneys, and nerves; therefore, maintenance of glucose homeostasis in the disease management of type 2 diabetes is crucial. Although multiple oral glucose-lowering drugs can effectively improve blood glucose levels in patients with type 2 diabetes, they may also cause hypoglycemia as a serious side effect because the glucose-lowering activity of these drugs is independent of the blood glucose levels of patients. If this side effect occurs frequently, it will lead to life-threatening cardiovascular and cerebrovascular complications. Currently, novel hypoglycemic drugs exhibit the unique, ideal property of promoting insulin secretion in a glucose-dependent manner without causing hypoglycemia (3). There is evidence that vasoactive intestinal peptide (VIP), a peptide hormone, promotes insulin secretion in this manner. Therefore, VIP may act as an insulinotropic drug without increasing the risk of hypoglycemia following administration. One of the cell receptors associated with VIP is VPAC2, which regulates insulin secretion; thus, this interaction may potentially be key towards a novel therapy. This review summarizes the physiological significance of VIP in glucose homeostasis and the therapeutic potential of VPAC2-selective agonists in the treatment of type 2 diabetes.

Production of VIP and the associated receptors

VIP (a 28-amino-acid peptide) was first isolated from the duodenums of pigs in the early 1970s and was considered to be a gut hormone with vasodilatory effects (4). It was soon found to be widely distributed throughout the central nervous system and peripheral tissues (5, 6), including the brain, gastrointestinal tract, pancreas, immune organs and cardiovascular system (7, 8). Its distribution reveals its pleiotropic functions as a neurotransmitter, vasodilator, secretagogue and immunomodulator (9, 10). VIP is generated by the splicing and processing of its precursor from prepro-VIP, containing 170 amino acids (11), in addition to being processed into peptide histidine methionine in humans or peptide histidine isoleucine in other animals, which perform many common physiological roles (12, 13). VIP is a member of the secretin peptide family belonging to the same family as pituitary adenylate cyclase-activating polypeptide (PACAP) and glucagon and glucagon-like peptide-1 (GLP-1), which are coupled to specific G-protein-coupled receptors (GPCRs) on the cell surface (14, 15). VIP mainly relies on stimulating cyclic adenosine monophosphate (cAMP) production to play physiological roles in multiple tissues (16).

VIP exerts its physiological effects by binding to two receptor subtypes belonging to class B of GPCRs, namely VPAC1 and VPAC2 (17). PACAP can also activate the same receptors to exert functions, as its amino acid sequence shares 68% homology with that of VIP (18). PACAP has a specific receptor, termed PAC1, which exhibits a high affinity for it, whereas VIP and PACAP exhibit equally high affinity for VPAC1 and VPAC2 (19, 20). VIP receptors are expressed throughout the body and elicit a wide range of biological effects, such as relaxation of smooth muscles, promotion of gastrointestinal motility and regulation of hormone secretion (21). The two specific receptors for VIP are expressed on pancreatic islets (22), where VPAC1 is mainly responsible for glucagon secretion and hepatic glucose production (23, 24), while VPAC2 plays a role in improving glucose tolerance by stimulating insulin secretion. Additionally, VPAC2 appears to be less involved in the glycogenolytic pathways of the liver (22, 25). Based on these characteristics of VIP receptors, they can potentially be targeted for the treatment of type 2 diabetes.

Endocrine function and signaling of VIP in islets

Islets are innervated by parasympathetic, sympathetic, and sensory nerves (26). Immunohistochemistry has confirmed that VIP is localized in the postganglionic parasympathetic neurons, which originate from the dorsal motor nuclei of vagus nerves (27). VIP is released in islets after parasympathetic activation. VIP exerts two distinct endocrine functions in islets, namely glucagon secretion and insulin secretion, both of which are associated with glucose concentration (24). VIP-induced glucagon secretion occurs during hypoglycemia, while VIP exerts its role of promoting insulin secretion during hyperglycemia. In terms of glucose homeostasis, this review focuses on the function of VIP-stimulated insulin secretion. Glucose is the major factor triggering insulin secretion. Glucose breakdown increases ATP/ADP ratio in β-cells, closes ATP-dependent K+ channels, resulting in plasma membrane depolarization and the opening of voltage-gated L-type Ca2+ channels, which leads to an increased influx of Ca2+ to secrete insulin (28). The pathway of glucose-stimulated insulin secretion is modulated by other peptides, such as VIP, GLP-1 and PACAP. VIP amplifies the glucose-stimulated insulin secretion pathway...
through the cAMP cascade (29). VIP binding to VPAC2 receptors on β-cells preferentially interacts with Gα protein to activate adenylate cyclase (AC), resulting in a dose-dependent increase in cAMP (30, 31). As the second messenger, cAMP activates protein kinase A (PKA) and the Epac family of cAMP-regulated guanine nucleotide exchange factor (32, 33), both of which cause an increase in intracellular Ca²⁺ levels and induce insulin secretion (Figure 1) (22, 34). This mechanism is predominantly relevant in hyperglycemia, suggesting a glucose-dependent modality in the insulinotropic effect of VIP. The activity of other hormones to stimulate insulin secretion is also glucose-dependent, including GLP-1 and PACAP. VIP, GLP-1, and PACAP show equal effectiveness in stimulating insulin secretion (35). Interestingly, the combination of VIP and PACAP has no additive effect on the levels of insulin secretion, possibly because they share common receptors (36).

Roles of VIP and VPAC2 in the pancreas

Several VIP-related animal models designed to study pancreatic islets are summarized here to demonstrate the role of VIP in the pancreas. In VIP-knockout mice, fasting insulin levels were found to be significantly elevated compared to those in wild-type mice. Moreover, their blood glucose levels in the VIP knockout mice did not decrease but instead increased (37), suggesting insulin resistance in VIP⁻/⁻ mice. No change in islet mass was observed in these mice. It was speculated that this observation may be due to the activity of other structurally similar peptides, such as PACAP, which can activate VIP-associated receptors to replace VIP effects in VIP⁻/⁻ mice (38). Yet, glucose abnormalities were seen in VIP⁻/⁻ mice, indicating that VIP was involved in the regulation of glucose homeostasis. In fact, mice overexpressing VIP effectively exhibited reduced blood glucose levels and elevated insulin levels. This effect was seen after feeding but not while fasting (39). In vitro studies, VIP secretion was found to correlate with glucose concentration. The islets isolated from mice overexpressing VIP were individually exposed to media containing different concentrations of glucose. A high glucose concentration significantly promoted VIP secretion in pancreatic islets and enhanced glucose-induced insulin secretion (39). Hypoglycemia has not yet been identified in these models, which means that VIP induces insulin secretion in a glucose-dependent manner. In addition, VIP-overexpressing mice were still able to maintain glucose tolerance after removing 70% of the pancreas (39).

As mentioned above, when VIP binds to VPAC2 receptors, insulin secretion is induced. Therefore, VPAC2 receptor knockout mice represent an important model to evaluate the role of VPAC2 in pancreatic islets. In the oral glucose tolerance test, VPAC2-deficient mice showed a similar glycemic response...

![FIGURE 1](https://example.com/fig1.png)

**FIGURE 1**
VIP activates the VPAC2 signaling pathway in pancreatic islets. VIP binding to VPAC2 receptors on β-cells activates AC and increases the concentration of cAMP, which activates PKA and the Epac family. PKA triggers the closure of ATP-dependent K⁺ channels, resulting in plasma membrane depolarization, and the opening of voltage-gated Ca²⁺ channels, which leads to an increased influx of Ca²⁺. Activation of Epac mobilizes the release of Ca²⁺ from internal storage. Both the processes cause elevated intracellular Ca²⁺ levels and the release of insulin through exocytosis.
to wild-type mice, but insulin levels were significantly reduced in VPAC2-deficient mice (40). This suggests that the insulin sensitivity of VPAC2-deficient mice was markedly increased. This conjecture was confirmed in the insulin tolerance test. After insulin administration, blood glucose levels in VPAC2-deficient mice decreased to a greater extent than those in wild-type mice (40). These observations indicate that VPAC2 plays an important role in glucose homeostasis.

Previous studies have found that the effects of VIP on the pancreas are influenced by age and metabolic status (41). Islets from obese and lean mice of different ages were used to study the effect of VIP on insulin release. The results showed that VIP significantly enhanced insulin release in islets isolated from young obese mice, while islets from lean mice showed a very low sensitivity to VIP. In much older mice, VIP had no effect on insulin release, regardless of the sizes of the animals (obese or lean) (42). Therefore, age and metabolic status should be considered when discussing the effects of VIP on optimal insulin secretion (41).

Roles of VIP in the liver-to-pancreatic neuronal relay

Islet β-cell mass contributes to glucose homeostasis by inducing compensatory responses based on physiological requirements of insulin (43, 44). In an insulin-resistant environment, such as that caused by obesity, neuronal signaling from the liver is involved in the compensatory proliferation of islet β-cells (45). Imai et al. has proposed that the activation of hepatic extracellular-signal regulated kinase (ERK) is transmitted to the central nervous system by afferent splanchic nerves and then to the pancreas via efferent vagal nerves to promote β-cell proliferation (46); this hypothesis has been verified in different mouse models (47). Disruption of any portion of neuronal transmission from the liver to the pancreas inhibits β-cell proliferation, including inhibition of ERK phosphorylation, pharmacological deafferentation of splanchnic nerves, midbrain transsection, and pancreatic vagotomy, which demonstrates the role of a liver–brain–pancreas neuronal relay in islet β-cell proliferation. Although it has been shown that hepatic ERK activation triggers neuronal transmission from the liver to the pancreas, how its ERK signaling travels down via visceral nerves is unknown (46). In this neuronal transmission, vagal nerve signals activate the forkhead box M1 (FoxM1) pathway in β-cells, thereby promoting compensatory proliferation of β-cells and augmenting insulin secretion (Figure 2) (48). FoxM1 is a key transcription factor for cell proliferation (49, 50). It has been reported that vagal signals activate the upregulation of FoxM1-related genes in islets, including Foxm1, cyclin-dependent kinase 1 (Cdk1), cyclin A (CcnA) and polo-like kinase 1 (Plk1), as well as Mki67, all of which are involved in the cell cycle and induce β-cell proliferation (47).

To demonstrate the role of vagal signals in the liver–brain–pancreas neuronal relay, mouse islets were treated with a combination of neurotransmitters released from vagus nerves, including acetylcholine (ACh), VIP and PACAP (26); the results showed that they indeed promoted β-cell proliferation. Additionally, gene expression analysis showed that the expression levels of FoxM1-related genes and Mki67 gene were significantly increased (47). To explore the role of each of these neurotransmitters in the FoxM1 pathway, they were used individually to treat rat isolated islets, the above outcome was not observed. Meanwhile, when ACh was removed from the
combined treatment of multiple neurotransmitters, no upregulation of these genes was observed in pancreatic islets, suggesting that ACh plays a decisive role in the FoxM1 pathway. Upon combined treatment of islets with ACh plus VIP or PACAP, the expression levels of FoxM1-related genes and Mki67 gene were markedly increased, and the gene expression levels of ACh combined with VIP and ACh combined with PACAP were similar, causing significant proliferation of β-cells (47). ACh stimulates insulin secretion by activating Gq signaling (51, 52), while VIP and PACAP, as Gs-signaling activators, exert insulinotropic effects (30), implying that vagal signals may activate the FoxM1 mechanism by simultaneously stimulating multiple pathways to enhance β-cell proliferation. At present, the exact molecular mechanism of vagal factors and the FoxM1 pathway is unclear and needs to be further investigated. It has previously been demonstrated that the content of VIP in the pancreas of diabetic mice is increased, but its effect on stimulating insulin secretion is lower than that in normal mice (53). One plausible reason is a diminished VIP-receptor sensitivity in diabetic mice, and another can be attributed to the inhibition of FoxM1 pathway activation. Recently, it has been found that the reduced expression levels of ACh in diabetic mice with poor islet function are associated with pancreatic autonomic nerve damage (54, 55), which may attenuate the role of vagal signals in activating the FoxM1 pathway, indirectly suggesting that neuronal signaling from the liver to the pancreas is impaired in diabetic mice. This may imply that patients with type 2 diabetes have a disorder in the liver–brain–pancreas neuronal relay. Elucidation of the mechanism governing vagal signals in neuronal transmission from the liver to the pancreas could open up new treatment avenues for type 2 diabetes.

Development of VPAC2-selective agonists

The amino acid sequence of VIP is highly conserved in different species. The sequence of VIP is identical in mammals, except for the VIP sequence of guinea pigs, wherein 4 amino acids are replaced (56, 57). Amino acid substitutions also exist in some vertebrates such as chickens and frogs (58, 59), but this does not affect its biological activity. PACAP, the homolog of VIP, exists in two forms, specifically as a 38-amino acid peptide (PACAP38) and 27-amino acid peptide (PACAP27), with PACAP38 being its main form that plays a role in various tissues and organs (14). PACAP is one of the most conserved peptides in the secretin peptide family (60), with a consistent amino acid sequence in most animals except for one amino acid difference in chickens and frogs (15). The high sequence conservation of VIP and PACAP makes them attractive targets for disease treatment. Due to their structural similarity to GLP-1, VIP and PACAP are rapidly recognized and degraded by dipeptidyl peptidase-IV in vivo, contributing to their short half-lives, which results in transient effects (61). Although VIP and PACAP have been shown to induce insulin secretion, they can cause undesired redundant responses because of the wide distribution of their receptors in the body. These disadvantages constitute a technical barrier to the development of therapies for type 2 diabetes. Therefore, novel drug discovery and development of VIP analogues as well as a suitable drug delivery system are the main goals in developing VIP as hypoglycemic drugs.

Previous studies have demonstrated that the activation of VPAC2 receptors on β-cells is involved in promoting insulin secretion without triggering hepatic glycogenolysis and glucagon secretion, which results in hypoglycemic effects. Because of this, VPAC2 receptors can be a novel target for the treatment of type 2 diabetes. BAY55-9837 has been developed as a selective agonist for VPAC2, which was designed via site-directed mutations of VIP and PACAP (15, 62). It is a complete agonist for VPAC2 receptors and stimulates insulin secretion in a glucose-dependent manner. Islets isolated from rats and humans were placed into a medium at different glucose concentrations and supplemented with an appropriate amount of BAY55-9837. BAY55-9837 induced insulin secretion in islets in a medium containing 8 mmol/L glucose. However, its effect on insulin secretion was not observed in the 3 mmol/L glucose medium (62), effectively demonstrating that BAY55-9837 stimulates glucose-dependent insulin secretion. When BAY55-9837 was administered to rats either intravenously or subcutaneously, both the administration methods effectively induced insulin secretion and reduced blood glucose levels, and the hypoglycemic effect exhibited was similar to that of GLP-1. Additionally, there was no sign of hypoglycemia even with long-term continuous administration. Continuous subcutaneous injection of BAY55-9837 into rats resulted in a dose-dependent decrease in mean arterial pressure (62), which drew our attention. Unfortunately, BAY55-9837, similarly to natural VIP, exhibits a high sensitivity to dipeptidyl peptidase-IV, has poor metabolic stability (63), and deamidation at its asparagine sites results in rapid renal clearance (64). Therefore, this agonist would require continuous administration to maintain its pharmacological effectiveness, which limits its potential application in the treatment of type 2 diabetes.

To improve the stability of peptides, the recombinant peptide DBAYL (32 amino acids) was designed and produced using the gene recombination technology (65). The poor stability of BAY55-9837 is due to the high sensitivity of the H-S sequence at the N-terminus to dipeptidyl peptidase-IV, which prevents it from activating VPAC2 (61, 65). DBAYL adds a methionine to the N-terminus, blocking the N-terminal sensitive sequence, thus improving its stability and biological activity. DBAYL, a derivative of PACAP, activates VPAC2 to stimulate insulin secretion in a glucose-dependent manner, thereby effectively increasing glucose disposal (65). The accumulation of cAMP reflects the receptor potency of DBAYL. Its binding affinity to human VPAC1 receptors is only 1/1083 of its affinity to human VPAC2, and it has no activity against human PAC1 receptors. The half-life of DBAYL in mice is 1.98 h, which is approximately 23.8 folds that of BAY55-9837 in

Hou et al. 10.3389/fendo.2022.984198

Frontiers in Endocrinology frontiersin.org 05
prolong the half-life of BAY55-9837, but the duration of its VPAC2-selective agonists. In vitro (65, 66), prolonging the hypoglycemic time. In 3T3-L1 adipocytes treated with DBAYL, the expression of insulin receptor substrate 1 (IRS-1) and glucose transporter 4 (GLUT4) is significantly increased (65). IRS-1 is a key molecule for insulin signal transduction, and GLUT4 is an important carrier in glucose transport (67, 68). In addition, DBAYL increases the translocation of GLUT4, which is translocated from the cytoplasm to the cytomembrane in a non-insulin-dependent manner (65, 69). These proteins facilitate effective glucose uptake and utilization. Although DBAYL has some advantages, its half-life limits its use as a viable therapeutic drug for type 2 diabetes.

One approach to improve the stability of peptides is to attach polyethylene glycol (PEG) to peptides to prolong their action time. PEGylation increases the molecular weight of peptides, reduces renal clearance, prevents the degradation by peptidases, and maintains effective plasma concentration (70, 71). Therefore, the structure of BAY55-9837, which is prone to deamidation, was modified by adding a cysteine to the C-terminus to link it to PEG to produce its analogues, such as BAY (Q9Q28C32) PEG22 and BAY (Q9Q28C32) PEG43 (22- and 43-kDa PEGylated peptides, respectively) (72, 73). Both of them retained a high selectivity for VPAC2, extending their bioactivity. An intraperitoneal glucose tolerance test was performed in rats 3 h after subcutaneous injection of BAY (Q9Q28C32) PEG22 and BAY (Q9Q28C32) PEG43; both of these analogues induced substantially enhanced glucose disposal in rats. Moreover, a glucose tolerance test conducted 6 h later showed that only BAY (Q9Q28C32) PEG43 triggered a hypoglycemic effect. This indicates that the hypoglycemic action duration of BAY (Q9Q28C32) PEG22 and BAY (Q9Q28C32) PEG43 is at least 3 and 6 h, respectively (72). Compared with that of the original analogue BAY55-9837, these PEGylated peptides have significantly prolonged the half-lives. The structural stability of VPAC2-selective agonists remains to be improved, but it has been shown that the activation of VPAC2 on β-cells promotes insulin secretion in a glucose-dependent manner, which will inform future hypoglycemic drug innovations.

Application of nanoparticles on VPAC2-selective agonists

Amino acid site-directed mutagenesis and PEGylation can prolong the half-life of BAY55-9837, but the duration of its hypoglycemic effect is currently not sufficient to allow its use as a viable treatment for type 2 diabetes. The emerging nanoparticle technology can be used to create applicable drug delivery systems that may be able to prolong drug action time and reduce side effects (74); hence, the current advances in the development of nanoparticle-based VPAC2-selective agonists are considered in this review. Nanoparticles, as sustained-release carriers, can slowly release VPAC2-selective agonists to maintain their effective concentration in patients and continually stimulate insulin secretion without causing hypotension and other potential side effects caused by current drug candidates, which are related to infusion rate and high dose (75, 76). Nanoparticle conjugation with VPAC2-selective agonists can not only prolong the half-lives but can also facilitate a targeted drug delivery to improve drug efficacy (74, 77). Selenium nanoparticles (SeNPs) have been proven to delay the progression of diabetes owing to their antioxidant properties (78, 79). However, the unstable state of selenium can easily cause its transformation, this can be prevented by modifying SeNPs with chitosan to maintain its stability; additionally, chitosan is also biocompatible (80–82). Therefore, the developed VPAC2-selective agonists, including BAY55-9837 and DBAYL, have been inserted into chitosan-modified SeNPs (CS-SeNPs) to form BAY-CS-SeNPs and SeNPs-CTS-DBAYL, respectively, which are regarded as potential drugs for the treatment of type 2 diabetes (66, 83). BAY-CS-SeNPs exhibited a reduced renal clearance due to its increased molecular weight but showed a significantly extended half-life of approximately 20.81 h. In vitro medium, a rapid release of BAY55-9837 was observed in the first 12 h of BAY-CS-SeNPs administration, which stimulated insulin secretion in a glucose-dependent manner; the drug release gradually slowed down until completion at 72 h. The early rapid release phase may meet the high insulin requirement for maintaining postprandial glucose, while the later slow release may maintain nocturnal insulin levels (83). Taken together, the release rate of BAY-CS-SeNPs satisfies the time curve of human physiological demand for insulin. Similarly, SeNPs-CTS-DBAYL was able to rapidly release DBAYL during the first 12 h, followed by a slow release up to 48 h (66). Its release rate, similarly to that of BAY-CS-SeNPs, fulfills human physiological requirement for insulin. The half-life of SeNPs-CTS-DBAYL in mice was up to 14.12 h, 7.1-fold that of DBAYL. The DBAYL released from SeNPs-CTS-DBAYL was able to highly and selectively activate VPAC2, induce glucose-dependent insulin secretion, and increase insulin receptor expression and glucose uptake. The treatment of hyperglycemia using SeNPs-CTS-DBAYL was evidently better than that using DBAYL. It inhibited oxidative damage in INS-1 cells due to the presence of CS-SeNPs. Diabetic mice with regular SeNPs-CTS-DBAYL administration for long periods of time exhibited regulated blood glucose levels, improved insulin sensitivity and lipid profile, and preservation of the normal morphology of pancreas and adipose tissues (66).

The widespread distribution of VIP and its receptors is a major obstacle to the development of hypoglycemic drugs. Studies have found that exosomes are nanoscale vesicles secreted by a variety of cells and have a low immunogenicity and a high drug-carrying capacity (84, 85). Exosomes can serve as ideal sustained-release carriers that are highly stable and thus can prolong the half-lives of drugs. Currently, exosomes are being used in the treatment of tumors and have yielded promising results (86); hence, attempts to adapt them in the development of VPAC2-selective agonists are underway. Because exosomes lack the ability to target pancreatic islets, they were combined with superparamagnetic iron oxide nanoparticles (SPIONs), which have the ability to target a specific location in the body to produce the desired therapeutic efficacy.
SPIONs are biocompatible and can be targeted to transport drugs via an external magnetic force to the target location, thus reducing side effects (87). Recently, a new nanomedicine for VPAC2-selective agonists has been devised. It consists of BAY55-9837 loaded into SPIONs-modified exosomes named BAY-exosome-SPION (88). BAY-exosome-SPION targets and aggregates on β-cell surface under the action of a magnetic force, and the released BAY55-9837 binds to VPAC2 receptors on β-cells and enhances insulin secretion. During the release curve of the BAY-exosome-SPION, it was observed that BAY55-9837 was released rapidly during the first 5 h and continued to be released until 60 h later. Due to the presence of exosome-SPION, the half-life of BAY55-9837 in circulation was extended to 8.39 h and the plasma clearance rate was reduced (88), implying that the rapid degradation of BAY55-9837 was prevented, thereby reducing the frequency of administration. Diabetic mice were treated with BAY-exosome-SPION twice a day, and they showed significantly reduced glycosylated hemoglobin levels and body weights as well as improved lipid profiles after 8 weeks. Furthermore, no significant toxic damage was observed in mice treated with BAY-exosome-SPION, which indicated that BAY-exosome-SPION demonstrated a good biosafety profile in vivo (88). These nanomedicines exert ideal hypoglycemic effects through suitable drug delivery systems and possess unique advantages, paving new ways to improve VPAC2-selective agonists. The characteristics of the VPAC2-selective agonists mentioned above are summarized in Table 1. The developed VPAC2-selective agonists are currently in the early stages of in vitro and in vivo studies, and the clinical specificity and efficacy still need further research; hence, it would be a while before viable applications of these agents could be implemented in type 2 diabetes treatment.

TABLE 1  Structure and half-life of VIP and VPAC2-selective agonists.

| Peptide                  | Structure                                      | Half-life      |

Conclusion

Previous hypoglycemic drug and exogenous insulin administration reduces blood glucose levels regardless of the blood glucose levels in vivo, greatly increasing the risk of hypoglycemia. The emergence of novel hypoglycemic drugs circumvents this drawback. Several studies have demonstrated that the specific binding of VIP with VPAC2 receptors on β-cells can stimulate insulin secretion in a glucose-dependent manner, eliminating the risk of hypoglycemia. This characteristic has been used to design and produce VPAC2-selective agonists. In addition, VIP promotes β-cell proliferation through synergistic activation of the FoxM1 pathway in a liver–brain–pancreas neuronal relay, but the molecular mechanisms underlying this pathway still require further research. Currently, VPAC2-selective agonists are constantly being innovated to improve their stability and efficacy, which indicates the possibility of their successful clinical applications in type 2 diabetes treatment in the future.
