POSSIBLE GENERATION OF $\gamma$-RAY LASER BY ELECTRONS WIGGLING IN A BACKGROUND LASER

QI-REN ZHANG
School of Physics, Peking University, Beijing 100871, China

The possibility of $\gamma$–ray laser generation by the radiation of wiggling electrons in an usual background laser is discussed.

Key words: Quantum electrodynamics in a laser, Electron wave distortion in a laser, $\gamma$–ray laser generation.

PACS number(s):12.20.-m, 42.50.Ct, 42.55.Vc

I. INTRODUCTION

To extend the spectrum of lasers to the $\gamma$–ray range is a long dream for both nuclear and laser physicists. It means fantastic improvement of techniques, such as much more precise measurements of space-time, holography for nanometer size or even smaller objects, and so on. There are various proposals for its realization. We reviewed some of them[1], including those of using nuclear $\gamma$–radiations and those of using $\gamma$–ray emitted by wiggling charged particles. We preferred the way of using the radiations from charged particles wiggling in a periodically bent crystal[2,4]. However, this proposal assumes that the crystal is ideal. Contrarily, the real crystals are not ideal. They have lacunae and impurities. This point hurts the reliability of the proposal. Another problem is that, the theory used in this proposal is not fundamental, which also spoils its reliability. Moreover, to bend the crystal periodically in small space-time is not easy. Here we propose a way for the $\gamma$–ray laser generation, which keeps basic ideals of this proposal, but without its shortcomings.

Physically a laser is a classical limit of electromagnetic wave, simple and clean. It wiggles charged particles in a well-known way, therefore is an ideal wiggler for further laser generation, including those in the $\gamma$–ray range. The whole process may be described by a fundamental theory, it is quantum electrodynamics, the best theory in physics nowadays. We therefore reformed the quantum electrodynamics[5] for this purpose, to see whether it may offer a better way for the $\gamma$–ray laser generation or not. The main change is to substitute the laser state for the usual vacuum state, the latter was defined to be a state without any photon and charged particle. The quantization of electromagnetic field is now around a given laser instead of the usual vacuum state. Base wave functions for the electron field quantization are changed to the solutions of Dirac equation for electron in the given laser, instead of that in the usual vacuum. These new base wave functions are periodically distorted, showing the quantum wiggling of electrons in the laser. This is a new picture of quantum electrodynamics, equivalent to its other pictures. As in the original picture, the Hamiltonian of the system is also divided into two parts. One is for the free motion, another is the interaction between the free parts. But now, electrons are wiggling under the action of the applied laser. Their freedom only means that they do not emit or absorb photons. Photons now are quanta of the fluctuation of the electromagnetic field relative to the given laser. The laser, a given classical part of the electromagnetic field is subtracted. This free Hamiltonian is exactly handled like that in the original picture. Interaction Hamiltonian governs the emission and absorption of single photon by an electron. It is handled by perturbation. This is save because of the smallness of the fine structure constant $\alpha$. We see that the proposal is on a sound foundation. It is as sound as the usual form of the quantum electrodynamics.

On this foundation we find that, in a head on collision between a mono-energy electron beam and a laser, in a wide range of electron energy and laser frequency, a beam of $\gamma$–ray appears on the forward direction of the electron motion. It is almost completely polarized, monodirectional and monochromatic. It is therefore worthy to try the $\gamma$–ray laser generation in this way.

There has been a lot of works on the electron laser collisions, both theoretical and experimental[6–14]. Theoretical works are based on the Compton formula and Klein-Nishina formula for the Compton scattering[15–18], which are derived from the quantum electrodynamics in vacuum[19,20]. The coherence of photon states in the laser[21–27] is therefore totally overlooked. Experimental works found a way for generating intense $\gamma$–ray. It is by the Compton backscattering (CBS) of laser on relativistic electrons. Regrettably, the possibility of that the generated $\gamma$–ray may be a laser was not considered. The possible generation of $\gamma$–ray laser has not been recognized. We hope these imperfections may be remedied.

In section II we explain how a laser wiggles electrons and makes them emit $\gamma$–quanta. The physics is emphasized. Nevertheless, it is as quantitative as that given by the systematically quantum electrodynamical derivation done in[3]. Formulae for following calculations are given. In section III we show numerical results obtained by these formulae, explaining why we can generate $\gamma$–ray lasers in this way. Section IV is for the evolution of $\gamma$–ray intensity, because of the balance between the $\gamma$–quanta emission and reabsorption. Possible intensity limit is discussed. Section V is for proposals on further amplification of $\gamma$–ray laser. Section VI is for confirming the coherence of the generated $\gamma$–ray laser. Section VII is for conclusions.
II. QUANTUM WIGGLING AND PHOTON EMISSION OF ELECTRONS IN A LASER

A laser is a classical limit of an intense electromagnetic wave and is well described by a classical 4-potential. In the Coulomb gauge, a circularly polarized laser is described by the vector potential

$$A(x) = A(x_0 \cos[k(z-t)] + y_0 \sin[k(z-t)]).$$  \tag{1}$$

It is a plane wave circularly polarized in the $x - y$ plane and propagating along the $z$ direction, with a wave vector $k = k z_0$ and an amplitude $A$. $x_0$, $y_0$ and $z_0$ are unit vectors along $x$, $y$ and $z$ directions respectively. The Dirac equation for an electron in this laser is

$$i \frac{\partial \psi}{\partial t} = \{ \alpha \cdot (-i \nabla) + eA[\alpha_x \cos \varphi + \alpha_y \sin \varphi] + \beta m \} \psi, \tag{2}$$

with $\phi \equiv k(z-t)$. $e$ is the absolute value of the electron charge, and $m$ is the electron mass. Dirac matrices defined in Lurie’s book and the nature unit system ($e = \hbar = 1$ are used. The operator on the right hand side of this equation is time dependent. Fortunately, a time dependent unitary transformation generated by the operator $e^{-i k z t}$ removes this time dependence, in which

$$j_z = -i \frac{\partial}{\partial \varphi} + \frac{\Sigma_z}{2}$$  \tag{3}$$

is the $z$ component of the angular momentum of the electron. $\varphi$ is the azimuth angle of the electron, defined to be the angle between the projection of the electron radius vector on the $x - y$ plane and the $x$-axis. $\Sigma_z$ is the $z$ component of the Pauli matrices. The transformation

$$\psi_r = e^{-ikzt_j} \psi$$  \tag{4}$$

is a rotation around the $z$-axis with angular velocity $k$. The resulting picture is therefore called the rotation picture, and denoted by the subscript $r$. Multiplying $e^{-ikzt_j}$ on two sides of equation (2) from left, we obtain the wave equation

$$i \frac{\partial \psi_r}{\partial t} = \{ \alpha \cdot (-i \nabla) + eA[\alpha_x \cos(kz) + \alpha_y \sin(kz)] + \beta m + k j_z \} \psi_r$$  \tag{5}$$

in the rotation picture. The operator on the right hand side of this equation is no longer time dependent. We therefore have stationary solutions $\psi_r(x,t) = U(x)e^{-i\varepsilon t}$ for this equation. They satisfy the eigen-equation

$$\{ \alpha \cdot (-i \nabla) + eA[\alpha_x \cos(kz) + \alpha_y \sin(kz)] + \beta m + k j_z \} U = \varepsilon U,$$  \tag{6}$$

in which $U(x)$ is an eigenfunction and $\varepsilon$ is the corresponding eigenvalue. This equation is exactly solved, with

$$\varepsilon \equiv \varepsilon_n \equiv \varepsilon_{n,\sigma,\tau}(p_z, p_\perp) = E + \frac{e^2 A^2}{2(E - p_z)} + (\frac{\sigma}{2} - n)k$$  \tag{7}$$

and

$$U(x) \equiv U_n(x) \equiv U_{n,\sigma,\tau}(p_z, p_\perp; x)$$

$$= \frac{1}{2\pi} \exp \left\{ i \left[ p_z + \frac{e^2 A^2}{2(E - p_z)} \right] \right\} \times \left\{ \frac{eA}{2(p_z - E)} \left[ \alpha_x \cos(kz + \alpha_y \sin(kz) + i(\Sigma_\sigma \cos k z - \Sigma_\tau \sin(kz)) \right] \right\} \times \left( i^n J_n(p_\perp \rho) e^{-i\phi} P_+ + i^{n-\sigma} J_{n-\sigma}(p_\perp \rho) e^{-i(n-\sigma)\Phi} P_- \right) u_\sigma(0).$$  \tag{8}$$

$p_\perp, E = \tau \sqrt{p^2 + m^2}$ with $\tau = \pm 1, \sigma = \pm 1$ and $n = \text{integer}$ are parameters characterizing the solution. Sometimes $n$ is chosen to be the representative of these parameters. $j_n(\xi)$ is a Bessel function of order $\nu$ in variable $\xi$. In the cylindric coordinates $p_\perp, p_\perp, \varphi_\perp$ for the momentum $p$, with $p_\perp = p_\perp \cos \varphi_\perp$ and $p_\varphi = p_\perp \sin \varphi_\perp$, the bispinor in the plane wave solution of Dirac equation for a free electron is

$$u = u_+ + u_- e^{i\phi_\perp},$$  \tag{9}$$

in which $\chi_\sigma$ is an eigenspinor of $\Sigma_z$ with eigenvalue $\sigma$. For given $p_\perp$ and $p_\perp$, the bispinor $| \psi \rangle$ is characterized by $\sigma$ and $\phi_\perp$, therefore may be denoted by $u_{\sigma}(\phi_\perp)$. The bispinor $u_\sigma(0)$ at the end of eq. (5) is defined in this way. The projection operator $P_\pm \equiv \frac{1 + \gamma_2 \gamma_z}{2}$ gives $P_\pm u_\sigma(0) = u_\pm$. $(\rho', \varphi', z)$ in wave function are coordinates of the electron position, in which $(\rho', \varphi')$ are defined by

$$x' = x - \frac{eA}{k(p_\perp \rho_\perp)} \sin(kz) = \rho' \cos \varphi',$$

$$y' = y + \frac{eA}{k(p_\perp \rho_\perp)} \cos(kz) = \rho' \sin \varphi',$$

in which $\chi_\sigma$ is an eigenspinor of $\Sigma_z$ with eigenvalue $\sigma$. For given $p_\perp$ and $p_\perp$, the bispinor $| \psi \rangle$ is characterized by $\sigma$ and $\phi_\perp$, therefore may be denoted by $u_{\sigma}(\phi_\perp)$. The bispinor $u_\sigma(0)$ at the end of eq. (5) is defined in this way. The projection operator $P_\pm \equiv \frac{1 + \gamma_2 \gamma_z}{2}$ gives $P_\pm u_\sigma(0) = u_\pm$. $(\rho', \varphi', z)$ in wave function are coordinates of the electron position, in which $(\rho', \varphi')$ are defined by

$$x' = x - \frac{eA}{k(p_\perp \rho_\perp)} \sin(kz) = \rho' \cos \varphi',$$

$$y' = y + \frac{eA}{k(p_\perp \rho_\perp)} \cos(kz) = \rho' \sin \varphi',$$

These equations constitute a $z$-dependent linear coordinate transformation from Cartesian coordinates $(x, y, z)$ to $(x', y', z)$ in $x - y$ plane, followed by a transformation from rectangular coordinates $(x', y', z')$ to polar coordinates $(\rho', \varphi', z')$ in this plane. The factor $\frac{1}{2\pi}$ on the right hand side of solution (8) is a normalization constant. The set $U_{n,\sigma,\tau}(p_z, p_\perp; x)$ of all eigenfunctions is therefore orthonormal, so that

$$\int U_{n,\sigma,\tau}^*(p_z, p_\perp; x) U_{n',\sigma',\tau'}(p_z', p_\perp'; x) d^3x = \frac{1}{p_\perp} \delta(p_z - p_z') \delta(p_\perp - p_\perp') \delta(n, n') \delta(\sigma, \sigma') \delta(\tau, \tau').$$  \tag{12}$$

Since in this work we are interested only in the electron-laser interaction, always have $\tau = 1$, the eigenfunctions will be simply denoted by $U_n(x) \equiv U_{n,\sigma}(p_z, p_\perp; x) \equiv U_{n,\sigma,1}(p_z, p_\perp; x)$ in the following.

At the limit $A \to 0$,

$$U_{n,\sigma}(p_z, p_\perp; x) \to U_n^{(0)}(p_z, p_\perp; x) \equiv e^{ip_\perp z} \frac{\sqrt{\pi} J_n(p_\perp \rho) e^{-i\varphi} P_+ + e^{-i(n-\sigma)\varphi} P_-}{2\pi} u_\sigma(0),$$  \tag{13}$$

These equations constitute a $z$-dependent linear coordinate transformation from Cartesian coordinates $(x, y, z)$ to $(x', y', z)$ in $x - y$ plane, followed by a transformation from rectangular coordinates $(x', y', z')$ to polar coordinates $(\rho', \varphi', z')$ in this plane. The factor $\frac{1}{2\pi}$ on the right hand side of solution (8) is a normalization constant. The set $U_{n,\sigma,\tau}(p_z, p_\perp; x)$ of all eigenfunctions is therefore orthonormal, so that

$$\int U_{n,\sigma,\tau}^*(p_z, p_\perp; x) U_{n',\sigma',\tau'}(p_z', p_\perp'; x) d^3x = \frac{1}{p_\perp} \delta(p_z - p_z') \delta(p_\perp - p_\perp') \delta(n, n') \delta(\sigma, \sigma') \delta(\tau, \tau').$$  \tag{12}$$

Since in this work we are interested only in the electron-laser interaction, always have $\tau = 1$, the eigenfunctions will be simply denoted by $U_n(x) \equiv U_{n,\sigma}(p_z, p_\perp; x) \equiv U_{n,\sigma,1}(p_z, p_\perp; x)$ in the following.

At the limit $A \to 0$,

$$U_{n,\sigma}(p_z, p_\perp; x) \to U_n^{(0)}(p_z, p_\perp; x) \equiv e^{ip_\perp z} \frac{\sqrt{\pi} J_n(p_\perp \rho) e^{-i\varphi} P_+ + e^{-i(n-\sigma)\varphi} P_-}{2\pi} u_\sigma(0),$$  \tag{13}$$
\(\rho, \varphi,\) and \(z\) are cylindrical coordinates of the electron. The right hand side is a solution of Dirac equation for a free electron, and

\[
\sum_{n=-\infty}^{\infty} \frac{e^{-in\varphi}}{\sqrt{2\pi}} U_{n,\sigma}^{(0)}(p_z, x_p; x) = \frac{1}{\sqrt{(2\pi)^3}} e^{i p \cdot x} \psi \tag{14}
\]

is a plane wave solution of Dirac equation for a free electron of momentum \(p = p_z (\cos \varphi x_0 + \sin \varphi y_0) + p_z z_0,\) \(u\) is defined by eq.\(^\text{(9)}\). In the case of \(p_z = 0\), we have

\[
U_{n,\sigma}^{(0)}(p_z, 0; x) = \frac{\delta_{n,0}}{2\pi} e^{i p z \cdot u}. \tag{15}
\]

It is nonzero only when \(n = 0\). In this case, it is already a plane wave of electron with momentum \(p = p_z z_0\). Now we see the influence of the laser on the electron motion. It is distortions of the electron wave in \(x - y\) planes, periodically along the \(z\) direction, and the modulation of the periodicity along the \(z\) direction. It is the wiggling of electrons. Since it appears in the wave function instead in their trajectories, we call it quantum wiggling.

The wiggling electron radiates because of the interaction \(e \mathbf{A}'\) between the electron and the electromagnetic field fluctuation around the laser. \(\mathbf{A}'\) is the difference between the total electromagnetic vector potential and the vector potential \(\mathbf{A}\) of the laser. It is decomposed into various modes, each with a wave vector \(\mathbf{k}'\) and a polarization vector \(\mathbf{e}'\), perpendicular with each other in the Coulomb gauge, and denoted by \(\varepsilon' = (\mathbf{k}', \mathbf{e}')\). It is quantized. In the interaction picture, the wave function associated with a photon of mode \(\varepsilon'\) is

\[
\mathbf{A}'(x, t) = \frac{\mathbf{e}'}{\sqrt{(2\pi)^2 k'}} e^{i (\mathbf{k} \cdot \mathbf{x} - k't)} \tag{16}
\]

and its complex conjugate. In the rotation and interaction picture, the interaction matrix element for the electron transition from the state \(U_{n',\sigma}(p_z, 0; x)\) to the state \(U_{n,\sigma}(p_z, 0; x)\) and emitting a photon of wave vector \(\mathbf{k}'\) and polarization \(\mathbf{e}'\) is

\[
\langle p_z', p_z', \sigma', n'; \mathbf{e}', \mathbf{k}'|H_{\text{r}}^{(\text{vir})}|n, \sigma, p_z, 0\rangle = e^{i \xi_{n',\sigma, 1}(p_z', p_z', \sigma') + k' \cdot e_{n,\sigma, 0}(p_z, 0)} \int U_{n,\sigma}^{\dagger}(p_z, 0; x) d^3 x \int U_{n',\sigma}^{\dagger}(p_z', p_z, \sigma') d^3 x. \tag{17}
\]

In which

\[
\mathbf{k}' = [k'_x \cos(kt) - k'_y \sin(kt)] x_0 + [k'_z \sin(kt) + k'_y \cos(kt)] y_0 + k'_z z_0 \tag{18}
\]

and

\[
\mathbf{e}' = [e'_x \cos(kt) - e'_y \sin(kt)] x_0 + [e'_z \sin(kt) + e'_y \cos(kt)] y_0 + e'_z z_0 \tag{19}
\]

are \(\mathbf{k}'\) and \(\mathbf{e}'\) respectively in the rotation picture. They rotate around the \(z\) axis with an angular velocity \(k\). The rotation transformation makes the unperturbed Hamiltonian of the electron in laser time independent, and makes the perturbation of the electromagnetic field fluctuation on the electron periodically time dependent. These two changes work together results in the equivalence of the rotation picture with the original one, and makes the problem able to be handled by the usual time dependent perturbation.

Take \(\mathbf{e}_1' = \cos(\varphi x_0 + \sin \varphi y_0) - \sin \theta z_0\) and \(\mathbf{e}_2' = -\sin \varphi x_0 + \cos \varphi y_0\) to be a pair of orthonormal polarization vectors orthogonal to the wave vector \(\mathbf{k}'\), in which \(\theta\) is the angle between \(\mathbf{k}'\) and the \(z\) axis, \(\varphi',\) is the angle between the projection of \(\mathbf{k}'\) on the \(x - y\) plane and the \(x\) axis. The integral in the eq.\(^\text{(17)}\) has been analytically worked out \[\text{[Ref.]}\]. It gives

\[
\langle p_z', p_z', \sigma', n'; \mathbf{e}_i', \mathbf{k}'|H_{\text{r}}^{(\text{vir})}|n, \sigma, p_z, 0\rangle = \frac{e\delta(p_z' - k_z')}{\sqrt{(2\pi)^3 2k'_p}} \times \sqrt{\frac{1}{4EE'(E + m)(E' + m)}} \sum_{N' = -\infty}^{\infty} \sum_{\nu = 0, \pm 1} J_N - \nu (p_z' R') \times \left[ \delta_{\sigma, \sigma'} F_i^{(\nu)} e^{-i N \varphi_{i'}} + \delta_{\sigma, -\sigma'} G_i^{(\nu)} e^{i (\sigma - N) \varphi_{i'}} \right] \times \delta[p_z' - p_z + \frac{e A}{2}(R' - R)k + k'_z - Nk] \times e^{i n_0 (\varphi_{i'} + \pi)} e^{i \varphi_{i'} E' - E + \frac{\pi}{2}(R' - R)k + k'_z - Nk}, \tag{20}
\]

with \(R = \frac{e A}{\sqrt{(E - p_z)\pi}}\), \(R' = \frac{e A}{\sqrt{(E + m)\pi}}\).

\[
F_1^{(0)} \equiv - \cos \theta p_z' (E + m) - \sin \theta [(E' + m)p_z + (E + m)p_z' + \frac{1}{2}k^2 R'(p_z - E - m)(p_z' - E' - m)], \tag{21}
\]

and

\[
F_2^{(0)} \equiv - \cos \theta p_z' (E + m) - \sin \theta [(E' + m)p_z + (E + m)p_z' + \frac{1}{2}k^2 R'(p_z - E - m)(p_z' - E' - m)], \tag{22}
\]

with \(N\) an integer, its appearance and the summation over it in eq.\(^\text{[20]}\) come from the integration.

Suppose a free electron of momentum \(p = p_z z_0\) and spin \(\sigma/2\) comes from free past and meets a laser
on the way. It evolves according to Gell-Mann Low theory\cite{29} into the state $U_{n, \sigma}(p_z; 0; x)$. The above analysis shows, this state may transit to a superposition $\sum_{n'} e^{i\vec{p}' \cdot \vec{x}} U_{n', \sigma}(p'_z, p'_{\perp}; x)$ of electron states in the laser due to the electromagnetic interaction $H'_{\text{r1}}$, and emit a photon of momentum $k'$. The superposed electron state evolves once again in the laser, into the state $e^{i\vec{p}' \cdot \vec{x}} u_{\sigma'}$, of a free electron when it goes to the remote future. In the initial state, besides an electron in the state $U_{n, \sigma}(p_z; 0; x)$, there may be $N$ photons in the mode $(k', e_1')$. It is denoted by $|N, k', e_1'; p, \sigma\rangle$, with $p = p_z 0$. In the final state, the electron state has transited to $\sum_{n''} e^{i\vec{p}'' \cdot \vec{x}} U_{n'', \sigma'}(p''_z, p''_{\perp}; x)$, and the number of the photon in mode $(k', e_1')$ becomes $N + 1$. It is denoted by $|N + 1, k', e_1'; p, \sigma\rangle$. The interaction matrix element is now

$$\langle \sigma', p'; e_1', k', N + 1 | H'_{\text{r1}} | N, k', e_1'; p, \sigma \rangle = \frac{e}{2\pi \sqrt{2k'}}$$

$$\times \sqrt{\frac{N + 1}{4E'E(2 + m)(E' + m)}} \sum_{N'} \int J_{N' - \nu} (p'_z R') \times \left[ \delta_{\sigma, \sigma'} F_i^{(e)} e^{-iN\phi_{e'}} + \delta_{\sigma, -\sigma'} G_i^{(e)} e^{i(\sigma - N)\phi_{e'}} \right]$$

$$\times \delta[p' + k' - p - Nk + \frac{cA}{2}(R' - R)k]$$

$$\times e^{i[E' - E + \frac{cA}{2}(R' - R)k + k' - Nk)]} \right|$$

in which the factor $\sqrt{N + 1}$ makes the stimulated emission,

$$\delta[p' + k' - p - Nk + \frac{cA}{2}(R' - R)k]$$

$$= \delta(p'_z - p_z) \delta(p'_{\perp} - p_{\perp})$$

$$\times \delta[p'_z - p_z + \frac{cA}{2}(R' - R)k + k' - Nk]$$

is a 3-dimensional $\delta$-function.

In the first order perturbation, the transition amplitude of the process is

$$\langle \sigma', p'; e_1', k', N + 1 | T | N, k', e_1'; p, \sigma \rangle = -i \int_{-\infty}^{\infty} \langle \sigma', p'; e_1', k', N + 1 | H'_{\text{r1}} | N, k', e_1'; p, \sigma \rangle \delta[t]$$

$$= -i \frac{e}{\sqrt{2k'}} \sqrt{\frac{N + 1}{4E'E(2 + m)(E' + m)}}$$

$$\times \sum_{N'} \sum_{N = -\infty}^{\infty} J_{N' - \nu}(p'_z R')$$

$$\times \left[ \delta_{\sigma, \sigma'} F_i^{(e)} e^{-iN\phi_{e'}} + \delta_{\sigma, -\sigma'} G_i^{(e)} e^{i(\sigma - N)\phi_{e'}} \right]$$

$$\times \delta[p' + k' - p - Nk + \frac{cA}{2}(R' - R)k]$$

$$\delta[E' + k' - E - Nk + \frac{cA}{2}(R' - R)k]$$

$\delta$-functions give selection rules for non-zero transition probability. They are

$$p' + k' - p - Nk + \frac{cA}{2}(R' - R)k = 0$$

and

$$E' + k' - E - Nk + \frac{cA}{2}(R' - R)k = 0.$$
section 31 becomes
\[
\frac{d\sigma}{d\Omega_{k'}} = \frac{\alpha k^2 (N + 1)}{8\pi m^2 k|p_z|(E - p_z)(E + m)(E' + m)} \times \sum_{N' = -\infty}^{\infty} \left| \delta_{\sigma,\sigma'}e^{i\gamma} \cdot \mathcal{F}_{N'} + \delta_{\sigma,\sigma'}e^{i\gamma} \cdot \mathcal{G}_{N'} \right|^2 ,
\]
(32)
in which
\[
\mathcal{F}_{N'} = \sum_{i=1,2} \sum_{\nu=0,\pm 1} \epsilon_i^{(\nu)} J_{N'-\nu}(p'_i R') e_{\nu}' ,
\]
\[
\mathcal{G}_{N'} = \sum_{i=1,2} \sum_{\nu=0,\pm 1} \epsilon_i^{(\nu)} e^{i\phi_i^{(\nu)}} J_{N'-\nu}(p'_i R') e_{\nu}' ,
\]
(33)

For definite \(\sigma, \sigma'\) and \(N'\), the polarization of the outgoing photon is also definite. It is \(e_{\nu}' = \mathcal{F}_{N'}/\mathcal{F}_{N'}\) for \(\sigma' = \sigma\) or \(e_{\nu}' = \mathcal{G}_{N'}/\mathcal{G}_{N'}\) for \(\sigma' = -\sigma\), with \(\mathcal{F}_{N'} \equiv \sqrt{\mathcal{F}_{N'} \cdot \mathcal{F}_{N'}}\) and \(\mathcal{G}_{N'} \equiv \sqrt{\mathcal{G}_{N'} \cdot \mathcal{G}_{N'}}\).

III. \(\gamma\)-EMISSION AND \(\gamma\)-RAY LASER
GENERATION FROM WIGGLING ELECTRONS
IN AN USUAL LASER

Consider the head on collision between an electron beam and a circularly polarized laser. To be definite, we take the Titanium Sapphire Laser of wave length 660nm to 1180nm tunable. Take the middle, we set the wave length of the laser to be 785nm. This kind of facility may be found in many laboratories over the world. By compression, the pulse intensity of this kind of laser may be as high as \(2 \times 10^{26} \text{W/m}^2\) [30]. However, the theory derived above is valid only when the applied laser may be considered as a plane wave. The linear dimensions of the laser pulse have to be much larger than the wave length. It means the laser should not be over compressed. We would take a moderate intensity. It is \(10^{19} \text{W/m}^2\). The energy of the incident electrons is limited in the range \(10^6\) to \(10^9\) 3 MeV. It may be found in many laboratories too.

Now, a circularly polarized plane wave laser of wave length 785nm propagates along the \(z\)-direction. A beam of electrons, each with energy \(E\), moves towards \(-z\) direction. Electrons wiggle in the laser and emit photons. Equations 29 and 31 show that the emission probability decreases rapidly with the increase of the integer \(N\), because of the contribution of Bessel functions. We therefore confine ourselves in the case of \(N = 1\). Using 28 we may calculate the energy of the emitted photon. To do this we need the coherence amplitude \(A\) of the applied laser. If the radiation is fully coherent, we have
\[
\frac{eA}{mc} = \sqrt{\frac{\alpha \lambda^2 I}{\pi mc^3}} ,
\]
(34)
in which \(\lambda\) is the wavelength and \(I\) is the intensity of the laser. \(\lambda_c = h/mc = 0.386\)pm is the Compton wavelength of the electron. Fixing \(I = 10^{19} \text{W/m}^2\) and \(\lambda = 785\)nm, we get \(A = 1.5 \times 10^{-2} mc/e\). Figure 1 shows the calculated relation between the energy of the emitted photon on the forward direction of the incident electron motion and the energy of the incident electron, in the case of \(\lambda = 785\)nm and \(I = 10^{19} \text{W/m}^2\) for the laser.

\[
\frac{d\sigma}{d\Omega_{k'}} = \frac{1}{2} \sum_{i=1,2} \sum_{\sigma=\pm 1} \sum_{\sigma'=\pm 1} \frac{d\sigma}{d\Omega_{k'}} .
\]
(35)
Substituting parameters
\[
\lambda = 785\text{nm}, \ I = 10^{19} \text{W/m}^2, \ \text{and} \ E = 307\text{MeV}
\]
into equations 31 and 35, we obtain numerical results for the average differential cross section as a function of \(\theta\),
which is shown in the figure. The angular distribution for the $\gamma$-photon emission is very characteristic. Photons concentrate in the forward direction of the incident electrons, and form a very sharp peak on this direction. It means an almost mono-directional emission. The single valued relation between the energy and the direction of the emitted photon tells us, it also means an almost monochromatic emission. The stimulated emission makes positive feedback, and therefore makes a collapse of the distribution into an almost geometric line with very high intensity. This is the $\gamma$-ray amplification by stimulated emission of radiation. Using equations (21) and (22), we find, from the description at the end of the last section, that the polarization vector of the forward radiation emitted by electrons is certainly

$$e' = \frac{1}{\sqrt{2}}(x_0 - iy_0),$$

(37)

independent of the spin states of the incident electrons. The radiation emitted by wiggling electrons is therefore completely polarized. A radiation, even though mono-directional, monochromatic and completely polarized, does not necessarily mean a laser. A laser must have a nonzero coherence amplitude, like the amplitude $A$ of the laser. It requires that the photon number of the state is not certain. Theoretically, this is not a problem in our case. The stimulated emission makes the photon number in the final electromagnetic state uncertain. The radiation emitted by wiggling electrons should therefore be a $\gamma$-ray laser, to be confirmed by experiments.

On the other hand, the coherence amplitude $A = 1.5 \times 10^{-2}mc/e$ in our case here is small. We have seen, in this limit, the energy of the photon emitted by wiggling electrons in a laser with $N = 1$ approaches the energy of the final state photon in the corresponding Compton backscattering. We have also seen in huge number of numerical examples, that the average cross section calculated by e.g. eqs. (31) and (35) approaches the result of Klein-Nishina formula in the same limit. The results shown in Figures 1 and 2 are therefore qualitatively true also for CBS. The radiation generated by the usual Compton backscattering, in which the incident photons do not form a coherent state, is also mono-directional, monochromatic and completely polarized on the forward direction of the incident electron motion. It means, what has generated in the CBS experiments, might already be a $\gamma$-ray laser. It would be interesting to check this point carefully in old and new experiments.

IV. BALANCE BETWEEN EMISSION AND ABSORPTION, THE INTENSITY OF $\gamma$-RAY LASER

Suppose electron-laser collisions happen in a tube of cross section $S$ and length $L$, with $\sqrt{S} \ll L$. It is the active tube for the $\gamma$-ray laser generation. Electrons come from an accelerator, enter the tube at one of its ends, say end 1; then move to another end, say end 2, and exit from the tube there. The laser enters the tube at end 2, then propagates along an opposite direction in the tube to end 1, and exits there. In the tube, beside the incident laser, there are initial state electrons of density $n(l)$, the emitted $\gamma$-photons of density $N(l)$, and the final state electrons of density $n'(l)$, at the point $l$. $l$ is an one dimensional coordinate of this point, denoting its distance to the end 1 of the tube. Two processes occur in the tube. One is the emission of the $\gamma$-photon by an initial state electron, after emission the electron transits to its final state. Another is the absorption of the emitted $\gamma$-photon by a final state electron, an initial state electron reappears. The interaction Hamiltonian $H_{rr}$ in equation (29) is Hermitian. It makes the reciprocal theorem valid for the emission and absorption processes here. In the local approximation we limit $N$ to be the photon number in an unit volume around the position $l$ under consideration. It is $N(l)$. In this meaning we have

$$dN = [(N + 1)n - Nn']dl/\lambda_c,$$

(38)

in which $a = \frac{\partial N}{\partial n}/(N + 1)$ is a constant independent of position $l$. It is easily seen, that $n + N$ and $n + n'$ are constants. Taking initial conditions

$$N(0) = n'(0) = 0 \quad \text{and} \quad n(0) \equiv n_0,$$

(39)

we have

$$N(l) = n'(l) = n_0 - n(l).$$

(40)

Substituting them into equation (38), we obtain

$$\lambda_c \frac{dn}{dl} = a[2n^2 - (3n_0 + 1)n + n_0^2].$$

(41)

This is the evolution equation of the process. The solution $n(l)$ under the initial conditions (39) and, by eq. (40), also $N(l)$ and $n'(l)$ are obtained:

$$n(l) = n_0 \frac{\sqrt{n_0^2 + 6n_0 + 1} - n_0 - 1 + (\sqrt{n_0^2 + 6n_0 + 1} + n_0 + 1) \exp(-\sqrt{n_0^2 + 6n_0 + 1}al/\lambda_c)}{\sqrt{n_0^2 + 6n_0 + 1} - n_0 + 1 + (\sqrt{n_0^2 + 6n_0 + 1} + n_0 - 1) \exp(-\sqrt{n_0^2 + 6n_0 + 1}al/\lambda_c)},$$

(42)

$$N(l) = n'(l) = 2n_0 \frac{1 - \exp(-\sqrt{n_0^2 + 6n_0 + 1}al/\lambda_c)}{\sqrt{n_0^2 + 6n_0 + 1} - n_0 + 1 + (\sqrt{n_0^2 + 6n_0 + 1} + n_0 - 1) \exp(-\sqrt{n_0^2 + 6n_0 + 1}al/\lambda_c)}.$$
Take parameters (36), which have been used in making figure 2, we obtain $\lambda_c/a = 337\text{nm}$. For tube length $L = 1\text{cm}$, $aL/\lambda_c$ is already practically infinity. Eq. (33) shows, in this case, at the end 2 of the tube, the number density of $\gamma$-quanta in the generated $\gamma$-ray laser approaches a constant, which is about a half of the number density of the incident electrons. This is a result of the balance between emissions and absorptions of $\gamma$-quanta by the initial state and final state electrons respectively in the tube. The intensity of the output $\gamma$-ray laser is therefore almost determined by the intensity of the input electron current. For an electron beam of density $n_0 = 10^{18}/\text{m}^3$ and energy $E = 307\text{MeV}$, which may be found in many laboratories, the intensity of the output $\gamma$-ray laser is about $5 \times 10^{13}\text{W/m}^2$. It is meaningful.

To generate a more intense $\gamma$-ray laser by the head on collision between an electron beam and an usual laser, one needs a more intense electron beam. This situation is somewhat similar to the generation of an usual laser by the coherent decay of a dense aggregate of similarly excited atoms, without pumping. The intensity of the laser is therefore limited by the limit density of the laser generating medium. In our case, it is limited by the density of the electron beam. In the theory presented above, Coulomb interaction between electrons is totally omitted. This is not permissible if the density of the electron beam becomes too high. Denote the mean linear dimension occupied by an electron in the beam by $\gamma$. The Coulomb force between two neighboring electrons is $\alpha/r^2$ in the nature units. On the other hand, the electric force of an applied laser acting on an electron is $e\mathcal{A}k$, in which $A$ and $k$ are the amplitude and the circular frequency of the laser respectively. Therefore, the Coulomb interaction is permissible only when $r \gg \sqrt{\alpha/e\mathcal{A}k} \equiv r_c$. It means the number density $n$ of the electron beam has to be much less than the critical density $n_c = r_c^{-3}$. Take parameters (36), we obtain $n_c \approx 10^{23}/\text{m}^3$. To be save, we take $n_0 = 10^{23}/\text{m}^3$. It may generate a $\gamma$-ray laser of intensity $10^{18}\text{W/m}^2$, if technical difficulties may be overcome. For too dense electron beams, the space charge effect becomes important. To consider the collision between a laser and a dense electron beam with serious space charge, we have to essentially modify the theory presented above.

V. MULTI-SECTION LASERS, PUMPING AND RESONATOR, LINEAR AND CYCLIC INTENSIFIERS

The space charge problem may also be solved in a technical way. It is to divide one high density electron beam into many sub-beams with much lower densities, and inject them into the active tube from different entrances at different times. Entrances are opened on the wall of the tube, distributed along its length direction. The electron sub-beams are injected through them by suitably designed magnets so that the injected electrons move along central axis of the tube. The injection time is also controlled to let the injected electrons meet the already emitted $\gamma$-quanta as soon as they arrive the central axis, so that the stimulated emissions may continue. Figure 3 is a sketch map of the designation. We also open exits for electrons, one by one with the entrances, on the wall of the tube. After participating the emission and absorption of $\gamma$-quanta, electrons are removed from these exits by suitably designed magnets, just before new electrons being injected through the corresponding entrances.

The active tube is now constituted by its sections, each begins from an entrance and ends at an exit. The tube analyzed above is a single section one. We may analyze each section in a multi-section tube in a similar way. Let us concentrate on one section of the tube. $l$ denotes the distance between a point in the section and the entrance of this section. Start from equation (38). We need a modification for the initial conditions (39). The $\gamma$-quantum number density at the beginning of a section is $N(0) \equiv N_0 \geq 0$ in general, the equal mark works only for the beginning section. Equation (40) now is substituted by $N(l) = N_0 + n'(l) = N_0 + n_0 - n(l)$. The evolution equation is generalized to be

$$\lambda_c \frac{dn}{dl} = a[2n^2 - (2N_0 + 3n_0 + 1)n + n_0(n_0 + N_0)]. \quad (44)$$

This is slightly more complicated than equation (11), but is still analytically solvable. An analysis similar to that made in the section [1] shows, for the case with parameters (36), in a section of length $L \sim$ centimeters, after a balance between emissions and absorptions, the net increase of average photon number density in the $\gamma$-ray laser at the end of the section, is still a big portion of the number density $n_0$ of newly injected electrons.

At the beginning of the new section, the initial state electron number density restores its original value $n_0$, and the final state electrons are removed. It is similar to the pumping in the usual laser generation. The intensity of the laser is therefore multiplied by this mechanism. A $\kappa$ section tube makes $\kappa$ times pumping, and therefore intensifies the $\gamma$-ray laser, roughly say, by a factor of $\kappa$. For the applied laser with parameters (36), the section
length is of the order of centimeters, and the length of a 100 section tube is of the order of meters. It is acceptable.

For the incident electron beam of density \( n_0 = 10^{18}/m^3 \), the intensity of the final output \( \gamma \)-ray laser is of the order of \( 10^{15}W/m^2 \). If the density of the incident electron beam becomes \( n_0 = 10^{23}/m^3 \), we will have a \( \gamma \)-ray laser of intensity \( 10^{20}W/m^2 \).

The intensity of a multi-section \( \gamma \)-ray laser is also influenced by the intensity of the applied laser. More intense incident laser gives larger emission probability for an electron wiggling in it, which in turn gives larger coefficient \( \alpha \) in the evolution equation (44) and shorter section in the active tube. An active tube of given length may therefore contain more sections and give higher intensity for the \( \gamma \)-ray laser.

A long (several meters or several ten meters), thin and well collimated many section active tube also plays a role here, which was played by a resonator in the usual laser generation. It selects a definite mode of \( \gamma \)-radiation, with definite direction, therefore definite wavelength and definite polarization, to amplify by stimulated emissions. Other modes are washed out from the amplification, because of the positive feedback. A longer and thinner active tube makes the quality of the \( \gamma \)-ray laser better. We call this structure a linear intensifier of the \( \gamma \)-ray laser.

One may change the direction of a soft \( \gamma \)-radiation by Bragg-reflection, and therefore may arrange the sections of the active tube for amplifying this radiation in a cyclic way. In principle, this structure may make ceaseless amplification for the \( \gamma \)-ray by stimulated emission in a finite space, and reach a very high intensity. We call this structure a cyclic intensifier of the \( \gamma \)-radiation. Unfortunately, the Bragg-reflection works only for soft \( \gamma \)-radiations with wavelengths of the order of the lattice constants of some crystals, it is of the order of Angstroms. Only lasers composed of soft \( \gamma \)-photons may be intensified in this way. For an example, in the head-on collision between an usual laser and a beam of electrons with parameters

\[
\lambda = 785\text{nm}, \quad I = 10^{19}W/m^2, \quad \text{and} \quad E = 7.68\text{MeV}, \quad (45)
\]

the energy of the output photon on the forward direction of incident electrons is 1.424KeV, it is in the soft \( \gamma \)-ray range. We expect the \( \gamma \)-ray of this kind may be intensified by the cyclic intensifier to a rather high intensity.

Of course, it is not easy to work out these proposals. Many technical problems have to be solved before their realization.

VI. CONFIRMATION OF THE COHERENCE

Finally we have to confirm that the generated and amplified \( \gamma \)-ray is indeed a laser. The most direct way for this purpose is to measure its coherence amplitude \( A \), and to see whether it is nonzero or not. The equations (28) and (29) help us to do so. Taking reciprocals of two sides in these equations, subtracting the result of the latter from that of the former, we obtain

\[
\Delta \lambda' = \frac{\lambda' - \lambda_0'}{\lambda_0'} = \frac{(eA \sin \theta)^2}{(E - p_z)(E - k - (p_z + k) \cos \theta)} \quad (46)
\]

\( \Delta \lambda' = 2\pi/k' \) and \( \lambda_0' = 2\pi/k_0' \) are wavelengths of outgoing radiations in the electron-laser collision and in the usual Compton backscattering respectively. The coherence amplitude \( \lambda' = \frac{\lambda_0'}{\lambda_0} \) of the outgoing radiations.

Suppose the output soft \( \gamma \)-radiation generated in the electron-laser head on collision with parameters (45) is intensified to a high intensity of \( I = 10^{26}W/m^2 \) by a cyclic intensifier. A beam of electrons of energy \( E = 5.135\text{MeV} \) is injected into the radiation along its propagation direction. Electrons interact with the radiation and emit ultraviolet radiation on the direction against the \( \gamma \)-ray propagation. Equations (28), (28) and (16) show that, if the \( \gamma \)-radiation is completely coherent, the wavelength of the emitted ultraviolet radiation would be \( \lambda' = 351\text{nm} \), and the wavelength shift due to the nonzero coherence amplitude \( A \) would be \( 2.77 \times 10^{-3} \). They may be detected and checked by experiments, using normal optic techniques, well developed about a century ago, for the fine structure research in the atomic spectroscopy.

It is possible, that the \( \gamma \)-ray is constituted by parts. One forms a coherent state, it is the laser. Another is a non-coherent aggregate of photons. The variable \( I \) in the equation (44) is the intensity of the coherent part. To be definite, we call it the coherence intensity. Combining equations (31) and (44), we see

\[
\Delta \lambda' = \frac{\alpha\lambda^2 \sin^2 \theta}{\pi (E - p_z)[E + k - (p_z + k) \cos \theta]} \quad I \quad (47)
\]

in the nature unit system. The wavelength shift is proportional to the coherence intensity of the radiation. In the above example, we assumed that the radiation intensity equals its coherent intensity. The radiation, as a whole, is a laser. If there are non-coherent photons, the coherent intensity will be lower than the total intensity. It results in a smaller wavelength shift. In other words, smaller wavelength shift means uncomplete coherence. If in the above example a smaller wavelength shift, say \( \Delta \lambda'/\lambda_0' = 2.77 \times 10^{-4} \) is observed, one has to conclude that only one tenth emitted photons form a coherent state. Other photons are non-coherent.

VII. CONCLUSIONS

Based on quantum electrodynamics, we have shown that, both in the head on electron-laser collision and in the Compton backscattering, the emitted photons may form a \( \gamma \)-ray laser. The competition and balance between the emission and reabsorption of \( \gamma \)-quanta by electrons determine the evolution and therefore the output intensity of the \( \gamma \)-ray laser.
In electron-laser collisions, incident electrons, wiggled by the applied laser, emit $\gamma$-photons. The stimulated emissions amplify the $\gamma$-radiation, form the $\gamma$-ray laser. In this sense, the generated $\gamma$-ray laser is a Free Electron Laser (FEL). The new here is that the electron motion in the background laser is governed and exactly solved by quantum mechanics. Therefore, it is a Quantized Free Electron Laser (QFEL). This mechanism may also be understood in an usual way. The incident electrons are higher state systems in the background laser. They transit into final (lower) state and emit $\gamma$-photons. The stimulated emissions again make the $\gamma$-ray laser. Two understandings of the $\gamma$-ray laser generation are unified in quantum theory. In this way, ideas in the usual laser theory, such as pumping, resonator, positive feedback, and so on are usable in the analysis. By use of them, we propose some ways to intensify and qualify $\gamma$-ray lasers. Analytical and numerical estimations show that the possible generated $\gamma$-ray laser may be intense enough to be detected and researched. A way for measuring the coherence amplitude $A$, and therefore confirming the coherence of the $\gamma$-ray laser is proposed.
