(Dated: 8th May 2013)

We investigate adiabatic quantum pumping of chiral Majorana states in a system composed of two Mach–Zehnder type interferometers coupled via a quantum point contact. The pumped current is generated by periodic modulation of the phases accumulated by traveling around each interferometer. Using scattering matrix formalism we show that the pumped current reveals a definite signature of the chiral nature of the Majorana states involved in transport in this geometry. Furthermore, by tuning the coupling between the two interferometers the pump can operate in a regime where finite pumped current and zero two-terminal conductance is expected.

Introduction. Recently, a great amount of attention has been paid to the possibility of realizing Majorana quasiparticles in condensed matter systems. Majorana-like excitations have been predicted to exist in the ν = 5/2 quantum Hall state, p-wave superconductors, semiconductor–superconductor interfaces, and on the surface of topological insulators. Zero-bias conductance anomalies associated with localized Majorana excitations have been measured recently. Measurements of unconventional Josephson effects associated with these excitations have also been reported. In addition, unique signatures of chiral Majorana fermions have been predicted in Mach–Zehnder and Hanbury Brown–Twiss type interferometers through conductance and noise measurements. In this article, we propose and analyze an adiabatic Majorana quantum pump which can provide a conclusive evidence of the chiral nature of the Majorana modes.

Adiabatic pumping is a transport mechanism in meso- and nanoscale devices by which a finite dc current is generated in the absence of an applied bias by low-frequency periodic modulations of at least two system parameters (typically gate voltages or magnetic fields). In order for electrical transport to be adiabatic, the period of the oscillatory driving signals has to be much longer than the dwell time of the electrons in the system, T = 2πω−1 ≫ τdwell. Adiabatic quantum pumping refers to pumping in open systems in which quantum-mechanical interference of electron waves occurs. Recently, adiabatic topological pumping in a spin-orbit coupled semiconductor nanowire in proximity to a s-wave superconductor and subjected to a Zeeman field was studied. In this study, we consider an adiabatic quantum pump where the carriers responsible for transport are chiral Majorana fermions. A schematic of the proposed device is shown in Fig. 1. The pump consists of two superconducting islands supporting chiral Majorana edge states coupled via a quantum point contact. While the conductance in this system can be used to signal whether an unpaired Majorana bound state exists in the superconducting region or not (as was predicted in Refs. 23,24), it does not contain information about the chiral nature of the carriers. We show that, in contrast, the pumped current in this system exhibits definite and measurable signatures of the chiral nature of quantum transport. Furthermore, charge neutrality of the Majorana modes (limiting interactions with the environment) and the adiabatic operation of the pump makes this system attractive for studying quantum interference effects with Majorana modes in the presence of, in principle, negligible dephasing.

Majorana quantum pump. The superconducting and magnetic correlations on the surface of a topological insulator (as shown in Fig. 1 with ẑ being the unit vector in the out-of-plane direction), as well as the gapless states at the interfaces between them can be described by the Dirac–Bogoliubov–de Gennes (DBdG) Hamiltonian \( H = \Psi^\dagger H \Psi /2 \). In the Nambu basis where \( \Psi = (u_{\sigma}, u_{\delta}, v_{\delta}, -v_{\sigma})^T \), the Hamiltonian \( H \) is given by

\[
H = -i\hbar v_F \tau_z \otimes \hat{z} \cdot \hat{\sigma} \times \nabla - \mu \tau_z \otimes \sigma_0 + (\Delta \tau_+ \otimes \sigma_0 + \Delta^* \tau_- \otimes \sigma_0) + M \tau_0 \otimes \sigma_z. \tag{1}
\]
Here $\vec{f}$ and $\vec{r}$ represent vectors of Pauli matrices in spin space and particle–hole Nambu space respectively. Similarly, $\sigma_0$ and $\tau_0$ represent $2 \times 2$ identity matrices in spin and Nambu space, and $\tau^\pm = (\tau_x \pm i\tau_y)/2$. The first two terms in $\mathcal{H}$ describe the free surface states of the three-dimensional topological insulator with $v_F$ the Fermi velocity and $\mu$ the chemical potential. We choose the coordinate system such that this surface is parallel to the $x - y$ plane. The first term in the second line in $\mathcal{H}$ describes the superconducting proximity effect due to a s-wave superconductor. The magnetizations $M_t = (0, 0, M)$ and $M_s = (0, 0, -M)$ of the two ferromagnets (as shown in Fig. 1) describe the effect of Zeeman splitting as expressed by the last term in Eq. (1). Here $\Delta$ and $M$ are assumed to be spatially uniform. The excitation spectrum is gapped in both the superconducting and the magnetic regions. In the superconducting region the excitation spectrum is $E_k^S = \sqrt{(eV_F|k - \mu|^2 + |\Delta|^2)}$. In the magnetic region it is $E_k^M = \sqrt{v_F^2|\Delta|^2 - M^2} \pm \mu$ (which is gapped if $M > \mu$). Solutions of Eq. (1) also include the subgap chiral Majorana branch localized near the superconductor–ferromagnet interface with group velocity $v_m = v_F\sqrt{1 - \mu^2/M^2}/(1 + \mu^2/|\Delta|^2)$ \cite{23}. The amplitudes of these chiral Majorana modes are denoted by $\gamma_l$, $l \in \{1, 4\}$ in Fig. 1. The interface between regions with opposite signs of magnetizations supports two chiral Dirac fermion modes. One is the electron mode with amplitude $\phi^e$ and the other hole mode with amplitude $\phi^h$. Within the Landauer–Büttiker scattering matrix formalism we can relate the two incoming modes $\phi^e_{in}$ and $\phi^h_{in}$ with two outgoing modes $\gamma_1$ and $\gamma_2$ at the left tri-junction using $(\gamma_1, \gamma_2)^T = S(E)(\phi^e_{in}, \phi^h_{in})^T$. Particle-hole symmetry $[S(E) = S^*(E) \tau_2]$ along with unitarity $[(S^t)^{-1} = S]$ allows us to choose at $E = 0$

$$S = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ i & -i \end{pmatrix}. \quad (2)$$

Similarly we can relate the chiral Majorana modes $\gamma_3$ and $\gamma_4$ to outgoing electron and hole modes at the right tri-junction. In the following it is assumed that $S(E)$ is well described by its zero energy limit, which is appropriate for small energies $E \ll (v_m/v_F)\min(|\Delta|, |M|)$ and junctions with mirror symmetry\cite{23}.

The Majorana modes $\gamma_1$ and $\gamma_2$ are coupled to Majorana modes $\gamma_3$ and $\gamma_4$ via the Josephson junction between the two superconductors (denoted as SC$_1$ and SC$_2$ in Fig. 1). The junction acts as a quantum point contact (QPC) for the Majorana modes and can be characterized by a $2 \times 2$ scattering matrix, $(\gamma_3, \gamma_4)^T = S_{QPC}(\gamma_1, \gamma_2)^T$\cite{23}

where

$$S_{QPC} = \begin{pmatrix} r_1 & t_2 \\ t_1 & r_2 \end{pmatrix}. \quad (3)$$

Here $|t_1|^2 = 1 - |r_1|^2$ and $|t_2|^2 = 1 - |r_2|^2$. The properties of this QPC can be tuned by changing the phase difference $\phi_1 - \phi_2$ of the Josephson junction (as shown in Fig. 1) or by altering its shape. As explained in Ref. 23, this Josephson junction describes superconductors weakly coupled by single electron tunneling at a point. Particle–hole symmetry and unitarity imply that $r_1$ and $t_2$ are real coefficients. Below we assume a symmetric Josephson junction and set $r_1 = r_2 = r$, and $t_1 = -t_2 = t$. The incoming electrons and holes can be related to the outgoing electrons and holes by the full scattering matrix of the system $S_{QPC}(\phi^e_{in}, \phi^h_{in})^T = S_{RL}(\phi^e_{out}, \phi^h_{out})^T$. The scattering matrix $S_{RL}$ can be decomposed into $S_{RL} = S^1S_2S_{QPC}S_1S_2$, where

$$S_1 = \begin{pmatrix} e^{i\beta_a} & 0 \\ 0 & e^{i\beta_b} \end{pmatrix}, \quad S_2 = \begin{pmatrix} e^{i\beta_c} & 0 \\ 0 & e^{i\beta_d} \end{pmatrix}, \quad (4)$$

de note the contribution from the phase shifts $\beta_k (k \in \{a, b, c, d\})$ picked up by the Majorana modes by traversing the $k^{th}$ arm of the interferometer. The relative phase shifts $\beta_1 = \beta_2 = \beta_3 = \beta_4$ for every vortex enclosed, a Berry phase of $\pi$ for spin-1/2 particles and the dynamical phase. Similarly, $\beta_c - \beta_d = \beta_2 = \pi n_{v_2} + \pi + E\delta_{\tau_1}/h$. Here $n_{v_1}$ and $n_{v_2}$ denote the number of vortices in SC$_1$ and SC$_2$, $\delta_{\tau_1} = L_1/(v_m)_{a} - L_2/(v_m)_b$, $\delta_{\tau_2} = L_3/(v_m)_{c} - L_4/(v_m)_d$ where $L_k$ and $(v_m)_j$ are the length and the velocity of the chiral Majorana mode in the $k^{th}$ arm of the interferometer. We then obtain

$$S_{RL} = e^{i(\beta_h + \beta_a)} \begin{pmatrix} \eta^+_1 r - i\eta^-_2 t & -\eta^-_1 r - i\eta^-_2 t \\ -\eta^-_1 r + i\eta^-_2 t & \eta^-_1 r + i\eta^-_2 t \end{pmatrix}, \quad (5)$$

where $\eta^\pm_1 = (1 \pm e^{i(\beta_1 + \beta_2)})/2$, $\eta^\pm_2 = (e^{i\beta_1} \pm e^{i\beta_2})/2$ and the $(2, 1)$-element of $S_{RL}$ indicates conversion of an incoming electron in the left lead to an outgoing hole in the right lead.

Adiabatic quantum pumping. In our device the adiabatically pumped current through the Mach–Zehnder interferometer is driven by periodic modulation of the phases $\theta_1$ and $\theta_2$ as $\theta_1(t) = \theta_1 + \delta\theta_1 \cos(\omega t)$ and $\theta_2(t) = \theta_2 + \delta\theta_2 \cos(\omega t + \alpha)$. The total pumped current $I$ into the right lead (see Fig. 1) can then be expressed as an integral over the area $A$ that is enclosed in $\{(\theta_1, \theta_2)\}$–parameter space during one period, and is given by the scattering matrix expression\cite{30,31}.

$$I_{p,R} = \frac{\omega e}{2\pi^2} \int_A d\theta_1 d\theta_2 \sum_{m \in L, n \in R} \mathrm{Im}\{\Pi_{nm}(\theta_1, \theta_2)\} \quad (6a)$$

$$= \frac{\omega e}{2\pi} \delta \theta_1 \delta \theta_2 \sin \alpha \sum_{m \in L, n \in R} \mathrm{Im}\{\Pi_{nm}(\theta_1, \theta_2)\}. \quad (6b)$$

Here

$$\Pi_{nm}(\theta_1, \theta_2) = \frac{\partial S_{RL}^e}{\partial \theta_1} \frac{\partial S_{RL}^{he}}{\partial \theta_2} - \frac{\partial S_{RL}^{eh}}{\partial \theta_1} \frac{\partial S_{RL}^h}{\partial \theta_2}, \quad (7)$$

Eq. (6b) is valid in the bilinear response regime where $\delta \theta_1 \ll 1$ and $\delta \theta_2 \ll 2$ and the integral in Eq. (6a)
becomes independent of the pumping contour. $S_{RL,nm}$ describes the scattering of a Dirac fermion in mode $m$ in the left (L) lead to a Dirac fermion in mode $n$ in the right (R) lead. The explicit adiabatic condition for this system is given by $\hbar \omega < \{ \Delta, M, h (v_{mn} a) / L_k \} (k \in \{a, b, c, d \})$.

After calculating the derivatives of the scattering matrix coefficients using Eq. (8) and taking the imaginary part of the product, we obtain for the pumped current into the right lead of the single-mode pump of Fig. 1,

$$I_{p,R} = I_0 \left( rt - 2rt \sin^2 \left( \frac{\theta_1}{2} \right) - t^2 \sin(\theta_1 - \theta_2) \right), \tag{8}$$

where $I_0 = (\omega e) / (4 \pi) \delta \theta_1 \delta \theta_2 \sin \alpha$. From Eq. (8), we see that the electron (hole) charge collected in the right lead is always mediated by the interference of two chiral Majorana modes (see also Ref. 32). Notice that we can rewrite the pumped current as a sum of two terms $I_{p,R}(\theta_1, \theta_2) / I_0 = I(0)(0,0) + I(\theta)(\theta_1, \theta_2)$ consisting of an Aharonov–Bohm flux–dependent part $I(0)(\theta_1, \theta_2)$, and a flux–independent part $I(0)(0,0)$. The latter is given by $I(0)(0,0) = rt$ which reaches its maximum value of $I(0)(0,0) = 1/2$ at $t = 1/\sqrt{2}$. The flux–dependent part is a sum of two terms. The second term on the right-hand side of Eq. (8) is proportional to $rt$ and only depends on $\theta_2$. This is a consequence of the chiral nature of transport: If we reverse the direction of transport, this term will only depend on the phase $\theta_1$. From Eq. (8) we also see that the QPC plays an essential role in generating a pumped current. For a closed QPC ($t = 0$) no net pumped current is generated.

For carriers in the low–energy regime, $E \ll \hbar / \delta \tau_1$, we can approximate $\theta_i = (n_i + 1) \pi$. For a transparent contact point, $t = 1$, the pumped current then reduces to $I_{p,R}(\theta_1, \theta_2) = 0$ for $\delta n_+ = n_{\text{ev}} - n_{\text{od}}$ integer and it achieves maximum values $I_{p,R}(\theta_1, \theta_2) / I_0 = \pm 1$ for $\delta n_-$ half-integer. In the latter, the pump produces a unit $I_0$ of pumped current which is also its maximum value (for $t = 1$). This is also true for $t = 1/\sqrt{2}$ at $\theta_1 = -\pi/2$ and $\theta_2 = 0$ (modulo $2\pi$). The pumped current reaches a global maximum value of $I_{p,R} / I_0 = \pm (1 + \sqrt{2}) / 2 \approx 1.2$ at $t = \sqrt{2} / (2 + \sqrt{2}) / 2$.

Figure 2 shows the pumped current as a function of the phase shifts accumulated while traveling around the first and the second superconducting islands for a fixed value of the transparency $t$ of the QPC. The pumped current $I_{p,R}$ clearly is a $2\pi$–periodic function with respect to $\theta_1$ and $\theta_2$. However, as expected from Eq. (8), the pumped current is not a symmetric function under exchange $\theta_1 \leftrightarrow \theta_2$. The pumped current oscillates between positive and negatives values, meaning that the interferometer transmits alternatively electrons and holes. As discussed above, in the low-energy regime the pumped current has values near zero when the phase difference $\theta_1 - \theta_2$ is an even or an odd multiple of $\pi$, see line (a) and (b) in Fig. 2. The asymmetry between the two phases can be seen from the difference between line (c) and (d) in Fig. 2. The pumped current exhibits maximum values at $\theta_1 = -\pi/2$ and $\theta_2 = 0$ (modulo $2\pi$), see dot (e).

Conductance. In this section we discuss the difference between the conductance and the pumped current in our system. This is of importance for being able to measure the pumped current, as the main bottleneck for its detection is the difficulty to distinguish between the two types of currents. Using the Landauer–Büttiker formalism, the conductance across the interferometer can be written as:

$$G(eV) = \frac{e^2}{h} \left( |S^{ee}_{RL}|^2 - |S^{he}_{RL}|^2 \right). \tag{9}$$

Using the scattering matrix Eq. (5), the conductance is then given by:

$$G(eV) = \frac{e^2}{h} \left( 1 - 2 \left| t^2 \sin^2 \left( \frac{\delta \theta}{2} \right) + r^2 \sin^2 \left( \frac{\delta \theta}{2} \right) \right| \right), \tag{10}$$

where $\delta \theta_{\pm} \equiv \theta_1 \pm \theta_2$. In the low–energy regime, $E \ll \hbar / \delta \tau_1$, the conductance reaches the limiting values:

$$\begin{array}{c|c|c}
\delta n_{\pm} & t = 0 & t = 1 \\
\hline
\text{even} & +e^2 / h & +e^2 / h \\
\text{odd} & -e^2 / h & -e^2 / h \\
\end{array}$$

where $\delta n_{\pm} \equiv n_{\text{ev}} \pm n_{\text{od}}$. When $\delta n_{\pm}$ is an even number the Majorana states traveling along the two paths are unperturbed and the right normal lead collects an electron. When $\delta n_{\pm}$ is an odd number, one of the Majorana modes has acquired an additional phase of $\pi$ and the right lead collects a hole due to crossed Andreev reflection in which a $2e$ charge is absorbed by the superconductors. In both situations, the conductance is sensitive to the number of vortices encircled in the interferometer. This is in agreement with the single Mach–Zehnder interferometer studied earlier 23,24.

As for the pumped current, the conductance has two contributions: an Aharonov–Bohm flux–independent

![Figure 2: (color online). Contour plot of the pumped current $I_{p,R}/I_0$ [Eq. (8)] as a function of the phases $\theta_1$ and $\theta_2$ for $t = 0.8$. (a) $\theta_2 = \theta_1$ line, (b) $\theta_2 = \theta_1 - \pi$ line, (c) $\theta_1 = 0$ line, (d) $\theta_2 = 0$ line, and (e) $\theta_1 = -\pi/2$ and $\theta_2 = 0$ point. The maximum (minimum) values $I_{p,R}/I_0 = \pm 1.12$.](image-url)
conductance has the same dependence on $\theta$ depend, resp., on the sum and difference of the phases, an electron. The flux–dependent term has two terms which conductance reveals no signature of the chiral nature of port from left to right and from right to left. Thus, the $\theta$ conductance is a $2\pi$–periodic function with respect to $\theta_1$ for transport from left to right and from right to left. Thus, the conductance reveals no signature of the chiral nature of transport.

Figure 3 shows the conductance in units of $e^2/h$ as a function of the phase accumulated in the first and second superconducting islands for a fixed value of the transparency of the point contact. Like the pumped current, the conductance is a $2\pi$–periodic function with respect to $\theta_1$ and $\theta_2$. An interesting situation to analyze is when the interferometer does not transmit any charge, i.e., $G(eV) = 0$. This happens in two different situations: first, when the point contact is completely transparent (reflective), $t = 1(0)$, and $\delta \theta_\pm$ is a half-integer of $\pi$; and second, when $t = r = 1/\sqrt{2}$, $\theta_1 = -\pi/2$ and $\theta_2 = 0$ (modulo $2\pi$). In both cases, the processes of transmitting an electron and transmitting a hole have the same probability to occur. Since these two processes have opposite charge contributions, on average the total charge collected in the right lead is zero. Interestingly, in the second case, at these same points in parameter space the pump generates a maximum current, as discussed earlier.

We thus predict three main differences between the conductance and the pumped current in this system: 1) Although the conductance and the pumped current both contain a flux–independent part and a flux–dependent part, the flux–independent part of the conductance is independent of any system parameters while the flux–independent part of the pumped current depends on the transparency of the point contact. 2) While the conductance is insensitive to the direction of transport, the magnitude of the pumped current depends on whether the current is collected in the right or left lead, thereby reflecting the chiral nature of the transport. 3) At certain points in parameter space (i.e. for certain values of $t$, $\theta_1$ and $\theta_2$), the conductance is zero, whereas the pumped current reaches maximum values.

The proposed pumping mechanism requires the phases $\theta_1$ and $\theta_2$ to be varied in a periodic manner. One way to achieve this would be by periodically varying the magnetic field in each superconducting island. Alternatively, the velocity of the chiral Majorana states could be changed, using the method proposed in Ref. 13.

Conclusions. To summarize, we have analyzed quantum pumping via Majorana fermions in a Mach–Zehnder interferometer formed by ferromagnetic and superconducting regions on top of a 3D topological insulator. We have shown that in the low-energy regime the pumped current, unlike the conductance, cannot be used to distinguish between an even or odd number of Majorana bound states at the vortex cores in the superconducting islands. The pumped current, however, can be used to reveal signatures of the chiral nature of transport, whereas the conductance is independent of the direction of transport. We have also shown that the pumped current reaches maximum values in certain regions of parameter space where the conductance becomes zero. Tuning the system into the latter regions thus creates chances for experimentally observing the adiabatically pumped current induced by Majorana modes in this system.
