The hepatocyte nuclear factor 18 gene (HNF1B) is responsible for maturity-onset diabetes of the young type 5 (MODY5), which is characterized by early-onset diabetes mellitus and urogenital malformations. HNF1B is expressed during visceral endoderm formation. We identified a disruption of the great pancreatic artery in a patient with MODY5 with no pancreatic body or tail. Our findings support the significance of HNF1B in the development of the pancreas.

Human Genome Variation (2016) 3, 16022; doi:10.1038/hgv.2016.22; published online 14 July 2016

Maturity-onset diabetes of the young (MODY; MIM#606391) was first reported by Fajans in 1960, as an early-onset form of mild diabetes with autosomal dominant inheritance. The minimum prevalence of MODY is estimated to be 108/1,000,000 in the general population in the UK. In Germany, MODY affects ~ 1% of the whole population. MODY5 among all clinically diagnosed MODY is reported to be the least common type of MODY. Pathogenic mutations have been detected in > 16 genes, the majority of which code transcription factors. The most common causes of MODY are mutations in HNF1A (hepatocyte nuclear factor-1a; MODY 3, MIM#600496), which encodes a transcription factor, and the second most commonly mutated gene is GCK (glucokinase; MODY2, MIM#125851), which encodes a glycolytic enzyme. Additional mutations are found in HNF4A (hepatocyte nuclear factor-4a; MODY1, MIM#600496) and HNF1B (MODY5, MIM#189907). MODY5 is frequently associated with renal cysts and/or other urogenital manifestations. Moreover, some cases with MODY5 develop associated with ketoacidosis, like type 1 diabetes mellitus. The prevalence of MODY5 among all clinically diagnosed MODY is reported to be 2–6%. More than 50 types of mutations are reported, comprising base substitutions, small insertions–deletions and whole-gene deletions. The majority of mutations occur in first four exons of the gene. Exons 2, 4 and the intron 2 splice site are mutation site hotspots.

We identified a 24-year-old female patient with a 17q12 hemizygous deletion including HNF1B. She had a sudden onset of diabetes mellitus. On admission, the patient had a normal level of consciousness, with temperature 36.8 °C, regular heart rate at 102 per minute, and blood pressure of 126/66 mm Hg. Anthropometric data were height 148 cm, body weight 43 kg and body mass index 19.6. No diabetic retinopathy was observed in either eye. Plasma glucose was 385 mg/dl, HbA1c was 16.7%. Antibodies to glutamic acid decarboxylase (GAD-Ab), insulin (IAA), and IA-2 were negative. Liver dysfunction was observed (aspartate aminotransferase 30 IU/l, alanine aminotransferase 39 IU/l, lactose dehydrogenase 155 IU/l, alkaline phosphatase 283 IU/l and γ-GTP 252 IU/l), but no renal dysfunction was detected (blood urea nitrogen 8.0 mg/dl, creatinine 0.36 mg/dl, negative for urinary protein). Markers for β-cell function (immunoreactive insulin 3.3 μU/ml (5–30 μU/ml), urinary-c-peptide immunoreactivity 12 μg/day (16–120 μg per day)) indicated severely decreased insulin secreting capacity. Although the initial presentation was acute onset, the diagnosis of type 1 diabetes mellitus was not likely. Younger age of onset without obesity, and a family history of diabetes mellitus through three generations were consistent with a clinical diagnosis of MODY (Figure 1a). She had renal cysts and lacked a pancreatic body and tail (Figure 2a). These manifestations strongly suggested a diagnosis of MODY5 and genetic testing was performed.

The study was approved by the Ethics Committee of Tokyo Women’s Medical University and performed in accordance with the principles of the Declaration of Helsinki. Informed consent was obtained from the subject before participation.

Genomic DNA was derived from peripheral blood monocytes and used for routine PCR-based direct sequencing for HNF1B, using ABI 3100 (Applied Biosystems by Life Technologies, Carlsbad, CA, USA). The nine exons, flanking introns and minimal promoter region of HNF1B were screened in both directions. None of the part of fluorescence electrophoresis was heterozygous, implying that she had only one allele in the entire HNF1B. Then genomic copy-number aberrations were examined by microarray-based comparative hybridization analysis using Human Genome CGH 244A 243504 probes, 6.4-kb interval (Agilent Technologies, Santa Clara, CA, USA) as described. Subsequently, a hemizygous deletion at chromosome 17q12 spanning 1.3 Mb, arr 17q12 (34,815,184–36,241,526) × 1 (bild19), the region including entire HNF1B (Figure 1b) was found. There is a family history of diabetes in an autosomal dominant trait, and her mother (II-7) and grandmother (I-4) were suspected as having the same deletion (Figure 1a). However, the mother and grandmother declined genotyping despite careful genetic counseling.

The first case of MODY5 was reported in 1997. Three affected family members who carried the mutation on exon 2 (R177X) in

**HNF1B** had early onset and an insulin-deficient type of diabetes mellitus. These three cases also had renal cysts and various degrees of renal dysfunction. Later, it was clearly demonstrated, based on a *Xenopus* embryo model, that renal malformation, including renal cysts, are caused by gain-of-function or loss-of-function mutations in **HNF1B** in humans. Additional urogenital manifestations, such as dysplastic kidney, including horse-shoe kidney, duplex kidneys and single kidney, bicornuate uterus, and agenesis of the vas deferens have been reported. **HNF1B** is also involved in the development of the ureters, which may explain stenosis of the ureter responsible for hydronephrosis. **HNF1B** is also responsible for renal cysts and diabetes syndrome (MIM#137920), which does not require diabetes mellitus as a diagnostic criterion. This region is also responsible for 17q12 deletion syndrome (MIM#614527) and 17q12 duplication syndrome (MIM# 614526). These syndromes are characterized by autism spectrum disorder and schizophrenia, and are independent from diabetes mellitus. Thus, **HNF1B**-related phenotypes are heterogeneous, and are considered a multi-system disorder. Moreover, some phenotypes are similar between cases with mutations in **HNF1B** and copy-number variations in 17q12 spanning 1.3 Mb, including **HNF1B**, suggesting a gene dosage effect as a molecular mechanism in combination with other genes in this region. The precise signaling pathways, however, are not fully elucidated. Clinical manifestations related to mutations in **HNF1B** have been intensively reviewed, especially urogenital tract malformations, but there are few reports of pancreatic manifestations.

The proband underwent magnetic resonance cholangiopancreatography (MRCP), which showed disruption of the main pancreatic duct. Interestingly, celiac artery angiography demonstrated aplasia of the great pancreatic artery and the transverse pancreatic artery (Figure 2b,c).

**HNF1B** and **HNF1A** are homeobox transcription factor family members with a highly conserved N-terminal DNA-binding domain and a more divergent C-terminal transactivation domain. Those two genes developed by duplication of an ancestral gene and **HNF1B** functions as a homodimer or a heterodimer with **HNF1A**. In mice, vHnf1 (mouse **HNF1B**) expression is uniquely detected in the primitive and visceral endoderm from embryonic days 4.5 to 7.5, and in the liver, pancreas and ureter buds at embryonic days 9.5–11. Expression of vHnf1 is also detected during neural tube formation, and in the developing lungs and genital tract. A vHnf1 deficiency in mouse embryos is lethal due to defects in visceral endoderm formation. Haumaitre et al. reported that a lack of vHnf1 results in pancreas agenesis by embryonic day 13.5. In earlier stages, the dorsal bud rudiment forms only transiently and lacks key transcription factors for proper development of the pancreas. In another study, Haumaitre et al. proposed that the absence of vHnf1 results in decreased Ptf1a expression, which leads to defects in the development of the ventral pancreas and a reduced dorsal pancreas. Partial loss of hnf1ba function in zebrafish also causes pancreas defects, and normal hnf1ab function is distinctly required for pancreas specification. Haumaitre et al. also suggested a common genetic program in relation with hnf1ba, with a narrow developmental time window, that specifies progenitors of the liver, ventral pancreas, gall bladder and associated ducts. The pancreatic head develops by fusion of the dorsal and ventral bud, and the pancreatic body and tail develop only from dorsal bud. Atrophy of the pancreas was detected by abdominal computed tomography in five of six cases with MODY5, but it was not clear whether these cases were due to atrophy or agenesis. To our knowledge, celiac angiography and MRCP of the pancreas including MRCP and celiac artery angiography in a patient with MODY5 associated with pancreatic abnormality has not been reported previously. This observation implies that the absence of a pancreatic body and tail are due to a developmental defect rather than to atrophy after development of the pancreas. The liver dysfunction observed in this patient is a typical feature of MODY5.

In conclusion, systematic evaluation of the pancreas including MRCP and celiac artery angiography in a patient with MODY5 associated with 17q12 hemizygous deletion provided important clues to the molecular mechanism of **HNF1B** in development of the pancreas in humans.

Maturity-onset diabetes of the young
N Iwasaki et al

Figure 2. Radiologic imaging. (a) Abdominal CT with enhancement. The pancreatic head is shown, but the body and tail of the pancreas are not observed in this slice. A small cortical renal cyst can be seen in the right kidney. (b) MRCP. The main pancreatic duct was not contrasted (normal appearance of a main pancreatic duct is indicated by the red dotted line). (c) Angiography of celiac artery. The catheter reaches the contrasted celiac artery, which bifurcates into the gastroduodenal artery and splenic artery. The great pancreatic artery, which bifurcates from the splenic artery, ends abruptly and the transverse pancreatic artery, which is a peripheral branch of the great pancreatic artery, is nonexistent (indicated by the red dotted lines). The silhouette of the pancreas is indicated by the yellow dotted line. CT, computed tomography; MRCP, magnetic resonance cholangiopancreatography.
