Significance Statement

The innate immune system is activated by neuronal death, and recent studies demonstrate that in zebrafish neuroinflammation is required for neuronal regeneration. The roles of inflammatory cytokines are being investigated, however, the function of the inflammatory protease, matrix metalloprotease Mmp-9, in neuronal regeneration is unknown. We show herein that in adult zebrafish retinal inflammation governs the proliferative phase of the stem cell-based regeneration of rod and cone photoreceptors and determine the specific roles for Mmp-9 in photoreceptor regeneration. This study provides the first mechanistic insights into the potential role of Mmp-9 and serves to link neuroinflammation, stem cell-based regeneration of photoreceptors and human photoreceptor disease.
Abstract

Brain injury activates complex inflammatory signals in dying neurons, surviving neurons, and glia. Here, we establish that inflammation regulates the regeneration of photoreceptors in the zebrafish retina and determine the cellular expression and function of the inflammatory protease, matrix metalloproteinase 9 (Mmp-9), during this regenerative neurogenesis. Following sterile photoreceptor ablation anti-inflammatory treatment suppresses both the number of injury-induced progenitors and regenerated photoreceptors. Upon photoreceptor injury, \textit{mmp-9} is induced in Müller glia, the intrinsic retinal stem cell, and Müller glia-derived photoreceptor progenitors. Deleting \textit{mmp-9} results in over production of injury-induced progenitors and regenerated photoreceptors, but over time the absence of Mmp-9 compromises the maturation and survival of the regenerated cones. Anti-inflammatory treatment in mutants rescues the defects in cone maturation and survival. These data provide a link between injury-induced inflammation in the vertebrate CNS, Mmp-9 function during photoreceptor regeneration and the requirement of Mmp-9 for the survival of regenerated cones.
Introduction
Inflammation modulates immune and nonimmune functions during tissue development, repair, and diseases (Deverman and Patterson, 2009; Ekdahl et al., 2009). Acute inflammation involves the secretion of proinflammatory cytokines and chemokines that recruit immune cells to the damaged tissue (Liddiard et al., 2011; Nathan, 2002). In the adult central nervous system of mammals, acute inflammation can activate signaling cascades in stem and progenitor cells that stimulate neurogenic proliferation and promote neurogenesis (Borsini et al., 2015; Ekdahl et al., 2009; Kizil et al., 2015; Kyritsis et al., 2014, 2012). Chronic inflammation, however, is detrimental, and results in secondary damage to neurons and, in severe cases, neurodegenerative diseases (Amor et al., 2010). Proper regulation of the inflammatory cascades in the central nervous system is critical both to maintain tissue homeostasis and successfully repair injuries.

Unlike mammals, which possess a limited capacity for tissue regeneration, zebrafish have an astonishing ability to regenerate tissues and organs, such as fins, heart, brain, and retina (Gemberling et al., 2013; Kizil et al., 2012; Lenkowski and Raymond, 2014). Studies using zebrafish have identified cellular and molecular mechanisms which may unlock the regenerative potential of mammalian tissues (Ueki et al., 2015). Such mechanisms include inflammation. In zebrafish acute inflammation is both necessary and sufficient to induce neuronal regeneration (Kyritsis et al., 2012).

In the zebrafish retina, Müller glia serve as intrinsic stem cells that underlie the ability to regenerate retinal neurons (Bernardos et al., 2007; Fausett and Goldman, 2006). Neuronal injury and death stimulate Müller glia to initiate a transient gliotic response, followed by partial dedifferentiation and entry into the cell cycle. Müller glia then undergo a single asymmetrical division to produce multipotent progenitors, which proliferate rapidly, migrate to areas of cell death and differentiate to replace the ablated neurons (Fimbel et al., 2007; Sherpa et al., 2008; Goldman, 2014; Gorsuch and Hyde, 2014; Lenkowski and Raymond, 2014).
retina, paracrine and autocrine signaling that engage Müller glia plays an essential role facilitating this regenerative neurogenesis (Nelson et al., 2013; Zhao et al., 2014). Following a photolytic lesion, dying photoreceptors secrete Tnf-α, which signals to Müller glia, which then respond by partial dedifferentiation, and synthesis of Tnf–α and entry into the cell cycle (Nelson et al., 2013). Mechanical lesions induce the expression of leptin and Il-6 family cytokines in Müller glia and progenitors and is required for injury-induced proliferation (Zhao et al., 2014).

Matrix metalloproteinase 9 (Mmp-9) is a secreted protease that plays a prominent role in proliferation, migration, and differentiation by acting on extracellular molecules, including adhesion molecules, growth factors and cytokines (Bonnans et al., 2014; Le et al., 2007; Masure et al., 1991; Parks et al., 2004; Vandooren et al., 2014, 2013b). In adult tissues, Mmp-9 is dramatically induced following various types of injuries (Vandooren et al., 2014, 2013b; Xu et al., 2018), including the central nervous system, inflammatory cytokines, such as Tnf–α and Il-1β, activate mmp-9 expression (Shubayev et al., 2006; Vecil et al., 2000). However, the complexities of Mmp-9 function suggest the role of Mmp-9 during tissue regeneration is likely tissue, substrate and injury context dependent (Hindi et al., 2013; Vandooren et al., 2014b; Ando et al., 2017; Xue et al., 2017). The cellular expression and function of Mmp-9 during photoreceptor regeneration in the zebrafish are unknown.

Here, we determine the general role of inflammation and the cellular expression and function of the matrix metalloproteinase, Mmp-9, during photoreceptor regeneration. We establish that inflammation governs the proliferation of Müller glia and Müller glia-derived progenitors. We show that mmp-9 is expressed in Müller glia, as they prepare to enter the cell cycle, and Müller glia-derived progenitors. Using a loss-of-function mutant, we determine that Mmp-9 negatively regulates the proliferation of Müller glia-derived progenitors. Finally, we demonstrate that following photoreceptor regeneration, Mmp-9 is required for the maturation and survival of regenerated cone photoreceptors.
MATERIALS AND METHODS

Animals
Wild-type, AB strain zebrafish (Danio rerio; ZIRC, University of Oregon, Eugene, Oregon) were propagated, maintained, and housed in recirculating habitats at 28.5°C and on a 14/10-h light/dark cycle. Animals used in this study were between 6 and 12 months of age. The transgenic reporter line, Tg[gfap:EGFP]mi2002, was used to identify Müller glia in retinal sections (Bernardos and Raymond, 2006). All experimental protocols were approved by the University of Michigan’s Institutional Animal Care and Use Committee (IACUC).

Light Lesions
To kill photoreceptors, fish were dark adapted, then exposed to high intensity light (ca. 100,000 lux) for 30 minutes, followed by exposure to constant light (ca. 30.000 lux) for 72 hours (Bernardos and Raymond, 2006; Taylor et al., 2015). After 72 hours fish were returned to the recirculating habitats and normal light/dark cycle.

Quantitative Real-Time PCR
Total RNA was extracted from dissected whole retinas using TRIzol (Invitrogen, Carlsbad, CA). Reverse transcription to cDNA was performed using 1 µg RNA (Qiagen QuantiTect Reverse Transcription kit; Venlo, Netherlands), and each qPCR reaction was performed with 6 ng cDNA and Bio-Rad IQ SYBR Green Supermix (Bio-Rad CFX384 Touch Real Time PCR Detection System; Hercules, CA).

Dexamethasone treatment
A previously described protocol was used suppress injury-induced inflammation (Kyritsis et al., 2012). Briefly, fish were housed in system water with 15 mg/L dexamethasone (Sigma, Cat# No: D1756) diluted in 0.1% MetOH. Dexamethasone-containing and control solutions were changed daily and fish were fed brine shrimp every other day.

Immunohistochemistry
Dissected eyecups were fixed overnight at 4°C in phosphate buffered 4% paraformaldehyde, cryoprotected with 20% sucrose, and embedded in optical cutting temperature (OCT) medium (Sakura Finetek USA, Torrance, CA). Immunohistochemistry (IHC) was performed as previously described (Taylor et al., 2015). 10-μm-thick sections, collected through the optic nerve head, were mounted on glass slides. Sections were washed in phosphate buffer saline with 0.5% Triton-x (PBST) and incubated in 20% heat-inactivated normal sheep serum for 2 hours (NSS; Sigma-Aldrich Corp., St Louis MO). Primary antibodies were applied overnight at 4°C. Sections were then washed with PBST and incubated in secondary antibodies for 1 hour at room temperature. Prior to IHC for BrdU, sections were immersed in 100°C sodium citrate buffer (10 mM sodium citrate, 0.05% Tween 20, pH 6.0) for 30 minutes and then cooled at room temperature for 20 minutes. Sections were then subjected to IHC as described above. IHC performed on whole retinas was conducted as described previously (Nagashima et al., 2017).

Prior to IHC, retinas were dissected from dark-adapted animals, flattened with radial relaxing cuts, fixed at 4°C overnight in 4% paraformaldehyde in 0.1M phosphate buffer with 5% sucrose. Wholemount retinas were isolated and immunostained following the protocol described in Nagashima et al. (2017). Antibodies used in this study and their concentrations are listed in Table 2.

**BrdU labeling**

Dividing cells were labeled with BrdU by housing animals in system water containing 5 mM BrdU for 24 hours (Gramage et al., 2015).

**In situ Hybridization**

In situ hybridizations were performed as previously described (Luo et al., 2012). Digoxigenin (DIG)-labeled riboprobes for rhodopsin and pde6c were generated from full-length cDNA clones (Luo et al., 2012; Ochocinska and Hitchcock, 2007), whereas riboprobe for mmp-9 was generated by PCR amplification using primers containing the T3 or T7 promoter sequences (David and Wedlich, 2001). mmp-9 (F): 5'
TAATACGACTCCTGAGGGATTCTCTACTTCTGCGGG 3'  mmp-9 (R): 5'
AATTAACCCTCACTAAAGGGCTTAATAAATTGTAAACAAG 3'.

Briefly, 10-μm-thick sections were hybridized with riboprobes at 55°C, incubated with an alkaline-phosphatase-conjugated anti-DIG antibody and visualized using Fast Red TR/Naphthol AS-MX (SIGMAFAST) as the enzymatic substrate. When *in situ* hybridizations were combined with BrdU IHC, sections were removed from the fast red solutions, rinsed and post-fixed in buffered 4% paraformaldehyde for 10 minutes then processed for BrdU IHC as described above.

**Production of custom antibodies**

Antibodies specific to zebrafish Mmp-9 were generated by Pocono Rabbit Farm & Laboratory (PRF&L, Canadensis, PA) as previously described (Calinescu et al., 2009). A 24 amino acid peptide was used as the immunogen CDIDGIQYLGYGRTGPEPTAPQPR; NCBI: AY151254. Polyclonal antibodies were affinity purified and confirmed by ELISA (data not shown). Western blots performed with retinal proteins using pre and post-immune sera confirmed the post-immune serum detected a 76 kDa band, the predicted size of Mmp-9.

**Western Blot Analysis**

Protein samples were obtained from whole retinas homogenized in RIPA lysis buffer (ThermoFisher Scienific, Waltham, MA) containing protease and phosphatase inhibitor cocktail (5872S; Cell Signaling Technology, Danvers, MA, USA). Proteins were separated in a 12% Mini-PROTEAN TGX Precast gel (BioRad; Hercules, CA) and transferred to a polyvinylidene difluoride (PVDF) membrane (GenHunter Corp., Nashville, TN). To block non-specific staining, membranes were incubated in 5% nonfat dry milk in Tris buffered saline containing 0.3% Tween-20 (TBST) for 2 hours. Membranes were incubated with the antibodies-containing solution overnight at 4°C. Blots were then washed in TBST and incubated with horseradish peroxidase-conjugated secondary IgG (1:1000) for 1 hour at room temperature. Antibody-bound protein was visualized using Pierce ECL Western blotting substrate (32106; ThermoFisher...
To visualize loading controls, blots were also stained with antibodies against actin. Images were captured using the Azure C500 (Azure Biosystems). Densitometry of protein bands was performed using ImageJ software (https://imagej.nih.gov/ij/).

**Zymography**

Protein samples were prepared as described for the Western blot analyses. Proteins were separated on 10% Zymogram Plus (Gelatin) Protein Gels, (ThermoFisher Scientific; Waltham, MA). Following electrophoresis, proteins were renatured in 1X renaturing buffer (ThermoFisher Scientific; Cat# LC2670) for 30 mins at room temperature, then incubated in 1X developing buffer (ThermoFisher Scientific; Cat# LC2671) overnight at 37°. Gels were rinsed in deionized water and stained with SimplyBlue SafeStain (ThermoFisher Scientific; Cat# LC6060). Gels were imaged with long-wave ultraviolet light using the Azure C500 (Azure Biosystems; Dublin, CA). Active recombinant human MMP-9 (Calbiochem; PF140) was used as a positive control. Densitometry of the digested bands was performed using ImageJ software.

**Purification and intraocular injection of TNF-α**

To express the soluble form of zebrafish Tnf-α, the pQE30 plasmid containing zebrafish Tnf-α cDNA was transfected into M15 cells (QIAGEN, Germantown, MD) as described previously (Nelson et al., 2014). IPTG (final concentration: 1 mM, isopropylthio-β-galactoside, Life Technologies; Carlsbad, CA) was used to induce Tnf-α protein expression. An empty vector, lacking the tnf-α cDNA, was used as the control. Control and Tnf-α samples were subjected to the same purification methods. Purified Tnf-α was diluted to 1 mg/ml. 0.5 μl of either control lysate or recombinant Tnf-α was intravitreally injected using a Hamilton syringe. Intravitreal injections were repeated every 24 hours, and total RNA was collected at 72 hours post injection (hpi).

**CRISPR-mediated gene mutation**

*mmp*-9 mutants were generated according to previously described methods (Hwang et al., 2013). ZiFiT software (available in the public domain at zifit.partners.org) was used to identify a
19bp sgRNA target sequence for *mmp-9* (GGCTGCTTCATGGCATCAA). Target sequence Oligo1- TTGATGCCATGAAGCAGCC and Oligo2- AAAC TTGATGCCATGAAGCAG were annealed and subcloned into the pT7 gRNA vector (Addgene ID: 46759). The pCS2 nCas9n vector (Addgene ID: 46929) was used for Cas9 synthesis. To produce RNAs, the MEGAscript T7 kit (Ambion: AM1354) and mirVana miRNA Isolation kit (Ambion: AM 1560) were used for the gRNA, whereas, mMesage mMACHINE SP6 kit (Ambion: AM1340) and RNeasy mini Kit from (Qiagen: 74104) were used for the Cas9 mRNA. Single cell-stage embryos were injected with a 2nL solution containing 100 pg/nl sgRNA and 150 pg/nl Cas9 mRNA. Founders (F0) were outcrossed to AB wild-type fish. Mutations were identified using screening primers (F: 5′- AAGTCTGCAACTACATATCAGC -3′, R: 5′- GTACACACTGAGATGCTGATAAG-3′) that flanked the *mmp-9* sgRNA target site. Standard protocols for PCR used Platinum Taq-HF polymerase (Invitrogen; Carlsbad, CA) with genomic DNA as the template. The purified PCR product was subcloned into the pGEM-T Easy vector (Promega, Madison, WI) for Sanger sequencing. Mutant and wild-type sequences were aligned using pairwise blast (National Center for Biotechnology Information [NCBI], Bethesda, MD, USA). Premature stop codons were identified by comparing predicted amino acid sequences for wild-type and mutants using the ExPASy translate tool (available in the public domain at [www.expasy.org](http://www.expasy.org)). F1 hybrids carrying a *mmp-9* mutation were in-crossed and homozygous F2 mutants were identified by a combination of Sanger sequencing and T7 endonuclease assays (New England Biolabs, Ipswich, MA) as previously described ([www.crisprflydesign.org](http://www.crisprflydesign.org)).

**Imaging**

Fluorescence images of retinal sections were captured using the Leica TCS SP5 confocal microscope (Wetzlar, Germany). Cell counts were conducted using z-stack images and analyzed with Imaris software (Bitplane, South Windsor, CT). Regenerated photoreceptors were identified by the colocalization of DAPI, BrdU, and the ISH markers *pde6c* (cones) or *rho* (rods).
In wholemount retinas cone photoreceptors were counted from max projection images taken through the cone photoreceptor inner segments.

**Experimental Design and Statistical Analyses**

For qPCR experiments, three independent biological replicates were collected at each time point, and each replicate contained six homogenized retinas from three fish (18 retinas/time point). Each biological replicate was run in triplicate. For each time point, average mRNA levels were represented as Log2 fold change, calculated using DDC_{T} method and normalized to the housekeeping gene, *gpiα*. Primers used for qPCR analyses are listed in Table 1. The statistical significance in mRNA levels between unlesioned and lesioned retinas was calculated using an ANOVA (JMP 9.0; SAS Institute, Inc., Cary, NC). A p-value ≤ 0.05 was considered significant.

Cells were counted in both radial sections and retinal wholemounts. In radial sections, cells were counted in three nonadjacent sections in each retina. The number of cells per retina were averaged, and averages were computed for control and experimental groups. In retinal wholemounts, cells were counted in five separate regions in each retina, sampling a totaling 5625 μm per retina. The average number of cells in control and experimental groups were then averaged. The statistical significance of the number of cells between control and treated retinas was calculated using a student’s t-test (GraphPad Prism Software, La Jolla, CA). A p-value ≤ 0.05 was considered significant.

Western and zymogram analyses consisted of three independent biological replicates, and each replicate contained six homogenized retinas from three fish (18 retinas per time point). Statistical significance between optical density values of bands in control and experimental groups was calculated using an ANOVA (JMP 9.0, SAS Institute, Inc., Cary, NC). A p-value ≤ 0.05 was considered significant.
RESULTS
The expression of inflammatory genes is induced by photoreceptor ablation

To characterize the inflammatory response during photoreceptor ablation and regeneration, qPCR was used to quantify the expression of inflammatory genes, mmp-9, tnf–α, tnf–β, il-8, nfκb1, and nfκb2, shown previously to regulate various forms of tissue regeneration in zebrafish (de Oliveira et al., 2013; LeBert et al., 2015; Nelson et al., 2013; Karra et al., 2015). The time course of gene expression follows closely the well-established time course for the injury response in Müller glia and the appearance of the Müller glia-derived progenitors and their subsequent differentiation into mature photoreceptors (Figure 1A; see (Gorsuch and Hyde, 2014)). Upregulation of gene expression can be detected by 8 hours post lesion (hpl), and the rising phase in expression corresponds to the period when Müller glia prepare to enter the cell cycle. Expression levels then slowly decline as the Müller glia-derived photoreceptor progenitors divide, migrate to the outer nuclear layer and differentiate into regenerated photoreceptors (168 hpl; Figure 1A). Interestingly, among these genes, mmp-9 shows the highest levels of expression, which is maximal at 48 hpl. Further, by 168 hpl mmp-9 levels are reduced to only about 70% of the peak value (ANOVA F-ratio = 22.23, p= .0001; Figure 1A). The pro-inflammatory cytokine, Tnf–α, has been posited to be responsible for initiating photoreceptor regeneration in zebrafish (Gorsuch and Hyde, 2014; Nelson et al., 2013), but at all time points in this assay, the levels of tnf–α expression were not significantly different from controls. Our assay for tnf–α failed to replicate previous results (Nelson et al., 2013), and we infer this is most likely a consequence of technical issues, perhaps reflecting the different assays used here and in Nelson et al. (2013) to detect tnf–α. Nonetheless, these data show that in zebrafish a photolytic lesion, which leads to photoreceptor death, induces rapid expression of characteristic inflammatory genes that follows a time course reflecting the well-described events that underlie photoreceptor regeneration. Further, the expression of mmp-9 remains significantly elevated as photoreceptor differentiation commences.
Inflammation regulates injury-induced proliferation and photoreceptor regeneration

To determine if inflammation regulates aspects of photoreceptor regeneration, the glucocorticoid steroid, dexamethasone (Dex), was used to suppress the inflammatory response (see, Kyritsis et al., 2012). To validate the effectiveness of the Dex treatment, the expression levels of inflammatory genes were quantified in control and Dex-treated groups. At 72 hpl, the expression of mmp-9, il-6, and nfκb1 were significantly decreased following dexamethasone treatment (p values = .0001, .0061, .0003, respectively; Extended Data Figure supporting Figure 2 labeled as Figure 2-1). Dex treatment did not suppress the expression of tnf-a, which was expected, given this gene was not significantly induced in the original assay. The reasons for the failure of the Dex treatment to suppress il-8 expression are unresolved.

Based on previous results (Kyritsis et al., 2012), assays of cell proliferation and photoreceptor regeneration were performed for control animals and animals treated with Dex. Dividing cells were labelled with BrdU between 24 and 48 hpl to mark progenitors that will give rise to regenerated photoreceptors, and regenerated photoreceptors were identified as BrdU-labeled nuclei in the outer nuclear layer (72hpl) or BrdU-labeled nuclei surrounded by in situ hybridization signal for either rho (rods) or pde6c (cones) (7dpl). At 72 hpl (Figure 1B, Methods), there was significantly fewer BrdU-labeled cells in Dex-treated retinas compared to controls (p= 0.0079; Figure 1C, D). At 7 dpl, there were significantly fewer regenerated rod and cone photoreceptors in Dex-treated groups compared to controls (Figure 2B, C; p=0.0012). These results indicate that, consistent with data showing the requirement for inflammation in neuronal regeneration in the forebrain of zebrafish (Kyritsis et al., 2012), inflammatory mechanisms also promote photoreceptor regeneration in the retina.

Müller glia and Müller glia-derived progenitors express mmp-9

Due to the varied roles played by mmp-9 in injured/regenerating tissues (Vandooren et al., 2014), and its persistent expression throughout the time-course of photoreceptor regeneration (Figure 1A), the specific function of Mmp-9 was investigated further. As a first step, in situ
hybridization was performed to identify the cellular patterns of expression of \textit{mmp}-9. This was undertaken using the Müller glia reporter line, \textit{Tg[gfap:EGFP]mi2002}, and BrdU labeling 24hrs prior to sacrifice. There is no detectable expression of \textit{mmp}-9 in unlesioned retinas. In contrast, by 24 hpl, \textit{mmp}-9 is expressed exclusively in Müller glia, but at a time-point prior to their entry into S-phase of the cell cycle (Figure 3A). By 48 hpl, \textasciitilde 97\% of BrdU-labeled Müller glia express \textit{mmp}-9 (Figure 3A, B, C). At 72 hpl, the expression of \textit{mmp}-9 decreases (Figure 3A, C), and the cellular expression shifts to the Müller glia-derived progenitors, as evidenced by the absence of eGFP in BrdU-labeled cells that express \textit{mmp}-9 (Figure 3A). These data indicated that photoreceptor ablation induces the expression of \textit{mmp}-9 in Müller glia, and this expression persists in Müller glia-derived progenitors. Further, these results suggest that \textit{mmp}-9 identifies the subset of Müller glia that enter the cell cycle in response to a retinal injury.

**Mmp-9 protein is present and catalytically active following photoreceptor death**

In tissues, Mmp-9 is synthesized and secreted in a pro-form, as a zymogen, then converted into an active protease (Chattopadhyay and Shubayev, 2009; Vandooren et al., 2013a). Western blot analysis was used to characterize the induction of protein synthesis and zymogram assays were used to determine the time course of protein synthesis and catalytic activity for Mmp-9 during photoreceptor regeneration (Vandooren et al., 2013a, 2013b). Mmp-9 is not detected in unlesioned retinas, consistent with the qPCR and \textit{in situ} hybridization data (Figure 1A, 3A, 4A). At 16hpl, the first time point sampled, the un-cleaved, pro-form of Mmp-9 is detected as an upper band in Western blots (Figure 4A). Mmp-9 levels peak by 24hpl, and both forms of Mmp-9 are detected. Mmp-9 levels decrease between 24 and 72hpl, and during this interval the protein mostly appears in a slightly lower band, consistent with the active form of the protein. Mmp-9 levels are undetectable by Western blot analysis at 5dpl (ANOVA F-ratio = 8.377, p =.0013) (Figure 4 A, B). To evaluate the catalytic activity of Mmp-9, the same protein samples as were used for the Western blot analysis were used for zymography (Chattopadhyay and Shubayev, 2009; Vandooren et al., 2013a). Recombinant, active human MMP-9 was used as a positive
control and shows strong catalytic activity as evidenced by the large negatively stained band. Unlesioned retinas contain no Mmp-9 catalytic activity. In contrast, the catalytic activity parallels the data from the Western blot analysis (ANOVA F-ratio = 11.870, p = .0003) (Figure 4C, D). Together, results from the Western blot and zymogram analyses show that catalytically-active Mmp-9 is induced by a lesion that selectively injures photoreceptors, and the time course of Mmp-9 synthesis and catalytic activity parallels the proliferative phases of photoreceptor regeneration. It is noteworthy that the peak of protein synthesis and catalytic activity is at 24hpl, which precedes the peak of mRNA synthesis (cf. Figures 4 and 1A), suggesting independent regulation of mmp-9 transcription and translation.

**Tnf-α is sufficient to induce mmp-9 expression in unlesioned retinas**

Tnf-α induces mmp-9 expression in a variety of tissues (Vandooren et al., 2014). In zebrafish, this cytokine is induced by death of photoreceptors and inner retinal neurons, and it is required for Müller glia to enter the cell cycle (Nelson et al., 2013). Therefore, the ability of Tnf-α to induce mmp-9 expression in the zebrafish retina was tested. Tnf-α or the elution buffer used to column purify Tnf-α were injected into the vitreous space of unlesioned eyes, and mmp-9 expression was quantified by qRT-PCR (Figure 5A). There was no induction of mmp-9 in eyes that were either uninjected or eyes injected with elution buffer only. In contrast, mmp-9 was strongly induced in the retinas of eyes that received intraocular injections of Tnf-α (p = 0.0229) (Figure 5B). stat-3, which serves as a positive control for injury-induced proliferation in the retina (Nelson et al., 2012) was also strongly induced by Tnf-α injections (p = 0.0344) (Figure 5C). These results indicate that during photoreceptor ablation Mmp-9 functions downstream of Tnf-α.

**CRISPR mutants lack Mmp-9 protein and catalytic activity**

To investigate the function of mmp-9 during photoreceptor regeneration, mutants were generated using CRISPR-Cas9 (Hwang et al., 2013), targeted to the mmp-9 catalytic domain in exon 2 (Figure 6A). The 19 base sgRNA produced several alleles, two of which were bred to homozygosity and characterized further, a 23bp deletion (designated mi5003; ZFIN,
and an 8bp insertion (designated mi5004; ZFIN, https://zfin.org/), respectively (Figure 6B). Individuals from the two lines were crossed to create compound heterozygotes to evaluate the potential for off target effects in either of the two independent lines (see next section). Each of the two mmp-9 lines carry a mutation that results in a frameshift that predicts premature stop codons (Extended Data supporting Figure 6 labeled as Figure 6-1). Retinas from mutants were characterized by Western blot analysis and zymography. Unlesioned retinas had no detectable Mmp-9 or catalytic activity (Figure 6C, D). As expected, following photoreceptor ablation, Mmp-9 protein and catalytic activity are present in wild-type retinas (Figure 6C, D). In contrast, there was trace Mmp-9 and catalytic activity in the mi5004 line, but no detectable Mmp-9 or catalytic activity in mi 5003 line (Figure 6 C, D). Based on these results, all subsequent experiments were conducting using the mi5003 line, though the basic observations reported here were confirmed in the mi5004 line (data not shown) and the compound heterozygotes (see below).

**Photoreceptor death results in overproduction of photoreceptor progenitors and regenerated photoreceptors**

We first sought to determine if there were any differences in the starting points for the injury-induced proliferation in the mmp-9 mutants. Therefore, we compared the number of Müller glia and the number of mitotic progenitors, which support persistent neurogenesis (Raymond et al., 2006), in wild-type and mutant retinas. This analysis showed that there were no differences between wild-type and the mi5003 line in the number of Müller glia or the level of intrinsic cell proliferation (Extended Data supporting Figure 7 labeled as Figure 7-1). To determine the consequence of Mmp-9 loss-of-function on retinal regeneration, wild-type and mutant animals received photolytic lesions, Müller glia-derived progenitors were labeled with BrdU between 48-72hpl, and BrdU-labeled cells were counted at 72 hpl. Relative to wild-type animals, mutants had significantly more BrdU-labeled progenitors at 72hpl (p = .0186) (Figure 7A, B). This over production of the Müller glia-derived progenitors was also observed in the compound
heterozygotes (Figure 7-1), confirming that the hyperproliferation observed in each independent line is not the consequence of off-target effects and these results can be ascribed solely to the loss of Mmp-9 function.

It is also well established that Mmp-9 can modulate cell migration (Parks et al., 2004). To determine if Mmp-9 loss-of-function alters migration of photoreceptor progenitors from the inner nuclear layer, where Müller glia reside, to the outer nuclear layer, which exclusively contains photoreceptor nuclei, animals were subjected to photolytic lesions, exposed to BrdU between 48 and 72hpl and allowed to survive to 7dpl, a time point where proliferation and migration are complete and photoreceptor differentiation has commenced. Qualitative inspection shows that Mmp-9 loss-of-function does not alter the migration of the Müller glia-derived progenitors (Figure 7A, C). Further, cell counts show that the over production of photoreceptor progenitors observed in mutants at 72hpl results in significantly more BrdU-labeled cells within the ONL at 7dpl ($p = .0001$; Figure 7B, D), and a significantly more double-labeled regenerated rod and cone photoreceptors ($p = .0301$ and $p = .0005$, respectively; Figure 7 E-G). Together, these data show that, in the absence of an injury, Mmp-9 loss-of-function has no impact on the proliferative potential of the adult retina or migration of Müller glia-derived progenitors. However, the hyperproliferation of injury-induced progenitors in mutants indicates that Mmp-9 functions as a negative regulator of proliferation among Müller glia-derived progenitors, though the mechanistic details through which this is accomplished are not yet known (see Discussion). Further, the parallel overproduction of photoreceptors at 7dpl indicates that Mmp-9 plays no apparent role in governing the timing of cell cycle exit or the onset of photoreceptor differentiation.

**Mmp-9 governs maturation and survival of regenerated cone photoreceptors**

The qPCR data showed that $mmp$-9 levels remain significantly elevated at the time injury-induced photoreceptor progenitors exit the cell cycle and begin differentiating into mature photoreceptors (Figure 1A). This suggested that Mmp-9 may have functional roles beyond regulating proliferation during the initial stages of photoreceptor regeneration. Therefore,
regenerated rod and cone photoreceptors were qualitatively and quantitatively compared in wild-type and mutants at 21dpl, a time point where regeneration is complete (Powell et al., 2016). For both groups, retinal sections were labeled with rod- and cone-specific antibodies and regenerated photoreceptors were counted in sections and whole mount preparations. These analyses showed there were no qualitative differences between wild-type and mutants in the appearance of regenerated rod photoreceptors (Figure 8A), and the initial over production of rod photoreceptors observed at 7dpl was present at 21dpl (Figure 8B, C).

However, at 21dpl, the maturation and survival of cones in mutant retinas were clearly compromised. Relative to controls, regenerated cones in mutants have shorter outer segments and appear to be fewer in number (Figure 8A, inset 8B, 8C). Counts of regenerated cones in tissues sections show the initial over production of cones, evident at 7 dpl, is absent (Figure 8C). Cones were also counted in retinal wholemounts (Figure 9). In the wholemounts, cones were identified by their prominent profiles in optical sections taken through the inner segments, visible when retinas are stained with an antibody against the tight junction protein, ZO-1 (Nagashima et al., 2017). In both wild-type and mutant retinas, cone photoreceptors in unlesioned retinas are characterized by the very precise lattice mosaic, a feature of cone photoreceptors in teleost fish (Nagashima et al., 2017; Figure 9A). Following photoreceptor regeneration, areas of the retina that contain regenerated photoreceptors are readily identifiable by the marked spatial degradation of the mosaic, though individual cone photoreceptors are remain readily identifiable (Nagashima et al., 2017). Counts of regenerated cones in wholemount retinas show that mutants have significantly fewer regenerated cones than wildtype animals (p=.0229) (Figure 9A, B). Finally, as an independent measure of the maturation of cone photoreceptors, Western blot analysis was performed using an antibody against the cone-specific transducin protein, Gnat-2 (Figure 9C; Lagman et al., 2015). As expected, Gnat-2 levels in unlesioned retinas are comparable in wild-type and mutant animals. In lesioned retinas, Gnat-2 levels begin to recover in wild-type animals by 14 dpl, and by 21 dpl values in wild-type
animals are nearly at the levels found in unlesioned retinas (Figure 9C, D). In contrast, Gnat-2 levels in mutants lag behind wild-type levels, and at 21dpl Gnat-2 levels in mutant animals are significantly less than in wild-types ($p = .0014$) (Figure 9C, D). Comparable measures specific to rod photoreceptors showed there were no differences between wild-type and mutant animals (data not shown). These results indicate that Mmp-9 also has a functional role during photoreceptor regeneration, well after injury-induced proliferation and the initial differentiation of regenerated photoreceptors is complete. Further, this function is specific to cones.

**Late anti-inflammatory treatment rescues the maturation and survival defect of regenerated cones in mmp-9 mutants**

MMP-9 is known to cleave inflammatory cytokines and, thereby may function to terminate cytokine signaling during the resolution phase of tissue inflammation. To determine if the defects in the maturation and survival of cone photoreceptors is a consequence of persistent inflammation, we treated mutants with vehicle or Dex between 3 and 13dpl to suppress the inflammatory response, beginning after the initial formation of Müller glia-derived progenitors and throughout the phase of photoreceptor differentiation and maturation (Figure 10A). Cone photoreceptors were then counted in retinal wholemounts at 21dpl from vehicle and Dex-treated mutants. The number of cones at 21dpl in vehicle-treated mutants approximates that shown above (Figure 9; Figure 10B). In contrast, there are significantly more regenerated cones in the Dex-treated mutants than in the vehicle-treated controls (Figure 10B, C; $p = .01$), restoring the number of regenerated cones nearly to that observed in wild-type animals. Further, regenerated cones in the Dex-treated mutants are noticeably more mature than in controls, as evidenced by their more regular arrangement and increased overall length and lengths of the outer segments (Figure 10D). Correlated with these data, activated microglia are present in the ONL of vehicle-treated mutants (Figure 10E), a notable feature of the early stages of photoreceptor death. These results suggest that the absence of Mmp-9 results in a persistent inflammation, which selectively compromises the survival and maturation of cone photoreceptors.
DISCUSSION
The results of this study are summarized in Fig. 11. In response to photoreceptor cell death, Müller glia undergo a single asymmetric division through interkinetic nuclear migration to produce progenitors, which rapidly proliferate, migrate and differentiate to replace the ablated photoreceptors (Fig. 11A, B). Dexamethasone-induced immunosuppression inhibits proliferation, resulting in diminished photoreceptor regeneration (Fig. 11C). Loss of Mmp-9 function effectively reverses the consequences of immunosuppression, resulting in hyperproliferation and overproduction of regenerated photoreceptors (Fig. 11D). However, the absence of Mmp-9 leads to defects in the survival and maturation of cone photoreceptors (Fig. 11D). Immunosuppression in mutants following photoreceptor regeneration rescues the maturation and survival defects (Fig. 11E). Based on these results, we conclude that inflammation is required during the proliferative phase of photoreceptor regeneration, and as a component of the inflammatory response, Mmp-9 provides inhibitory balance that refines this proliferative response. Finally, we conclude that Mmp-9 is required for the survival and maturation of regenerated cone photoreceptors.

The response of stem cells to inflammatory signals is required for regenerative neurogenesis (Fischer et al., 2014; Kyritsis et al., 2012; White et al., 2017). In the forebrain of adult zebrafish, immunosuppression inhibits the production of progenitors after traumatic lesion (Kyritsis et al., 2012). In the zebrafish retina, immunosuppression results in decreased migration of microglia into the outer retina during the regeneration of rod photoreceptors (White et al., 2017). In the chick, ablation of microglia completely suppresses the formation of Müller glia-derived retinal progenitors (Fischer et al., 2014). Our data are consistent with these reports and demonstrate that acute inflammation is a required component of neuronal regeneration in the vertebrate retina.

In response to photoreceptor injury and death, mmp-9 is rapidly induced in Müller glia, anti-inflammatory treatment significantly suppresses the mmp-9 expression, and the
proinflammatory cytokine, Tnf-α, a proinflammatory cytokine, is sufficient to stimulate mmp-9 expression in unlesioned retinas. This trio of results validates Mmp-9 as a component of the inflammatory response in the retina. Several previous reports showed that following neuronal death Müller glia secrete the inflammatory cytokines, tnf-a, leptin, and il-11 (Nelson et al., 2013; Zhao et al., 2014). Recent transcriptome and gene ontology analysis for Müller glia, isolated during photoreceptor injury and death, identified cytokine signaling and the immune response as activated pathways (Roesch et al., 2012; Sifuentes et al., 2016). However, in the mammalian retina, neuronal death leads to persistent active gliosis in Müller glia and failure of the spontaneous expression of intrinsic reprogramming factors. This limits the ability for neuronal regeneration (Bringmann et al., 2009, 2006; Reichenbach and Bringmann, 2013; see also Ueki et al., 2015). Our data add details to the innate immune response in the retina that is required for stem cell-based regeneration of photoreceptors. It is interesting to note that the activation of cytokine pathways is conserved in the transcriptomes of Müller glia in both zebrafish and mouse models of photoreceptor degeneration (Roesch et al., 2012; Sifuentes et al., 2016), suggesting that modulating intrinsic cellular mechanisms may be a therapeutic avenue to regenerate retinal neurons in mammals (Vetter et al., 2017).

Mmp-9 loss-of-function results in an increased number of Müller glia-derived progenitors, resulting initially in more regenerated photoreceptors. The overproduction of regenerated photoreceptors is interpreted simply to result from the overproduction of progenitors, and Mmp-9 plays no role in the timing of cell cycle exit or initial photoreceptor differentiation. There are at least three interpretations that explain the overproduction of photoreceptor progenitors. First, the absence of Mmp-9 may allow more Müller glia to enter the cell cycle. Previous studies showed that neuronal damage results in only 65-75% of the Müller glia entering the cell cycle (Nagashima et al., 2013). However, we demonstrated that mmp-9 was expressed only by dividing Müller glia. The absence of proliferation in mmp-9-negative Müller glia argues against the possibility that additional Müller glia are recruited to the cell cycle. Second, in the mmp-9
mutants Müller glia may undergo more than a one round of cell division, thereby increasing the size of the initial pool of Müller glia-derived progenitors, which then divide at a normal rate. We do not favor this possibility, given a single asymmetric division among Müller glia is a hallmark of regenerative neurogenesis in the zebrafish retina. Third, in the mmp-9 mutants, proliferation of the Müller glia-derived progenitors is accelerated. We view this the likeliest of the three possibilities, and hypothesize that, as an extracellular protease, Mmp-9 regulates the concentration of cytokines and/or growth factors that regulate cell cycle kinetics within the niche of progenitors that cluster around each parental Müller glia (Bosak et al., 2018; Le et al., 2007; Manicone and Mcguire, 2008; Parks et al., 2004; Luo et al., 2012; Vandooren et al., 2013b). In the absence of Mmp-9, excess mitogenic signals lead to accelerated proliferation. Finally, we speculate that in regenerating tissues the magnitude of the inflammatory response serves to quantitatively match the number of injury-induced progenitors to the degree of the cell death.

Recently, Kaur et al (2018) demonstrated a regulatory feedback loop involving Shh signaling and Mmp-9 during retinal regeneration in zebrafish. Pharmacological and genetic suppression of Shh signaling inhibited the proliferative response of Müller glia and their progenitors. This was accompanied by up-regulation of mmp-9 and the repressor of proliferation, insm1a (Kaur et al., 2018; Ramachandran et al., 2012). The hyperproliferation we observed in the mmp-9 mutants is consistent with their proposed model. When Shh signaling declines, progenitors increase secreted Mmp-9, which then degrades extracellular factors that facilitate proliferative competence, resulting in increased insm1a and exit from cell cycle. In this model, the absence of Mmp-9 would fail to degrade factors that stimulate proliferation, leading to hyperproliferation. The positive feedback loop between Shh signaling and Mmp-9 suggests that Shh and HB-EGB, factors that function upstream of insm1a, may be proteolytic substrates for the Mmp-9 (Wan et al., 2012).

An inconsistency in the Kauer et al., (2018) study is their observation that morpholino inhibition of Mmp-9 action decreases the production of Müller glia-derived progenitors. This
report is inconsistent with our data from the *mmp-9* mutants and raises the possibility that (1) the reliance on morpholinos, with the recognized potential for off-target effects (Schulte-Merker and Stainier, 2014; Kok et al., 2015), may be the origin of these inconsistent data, or (2) their non-sterile injury paradigm, which allows bloodborne factors and cells to invade the retina, may result in the activation of signaling pathways not present in the retina following a photolytic lesion.

In the Mmp-9 loss-of-function mutants, survival and maturation of regenerated cone photoreceptors are compromised. It is well established that chronic inflammation is a risk factor for photoreceptor dystrophies in humans, such as retinitis pigmentosa and age-related macular degeneration (AMD; Kauppinen et al., 2016; Chen and Xu, 2012; Whitcup et al., 2013; Yoshida et al., 2013). A subset of patients with AMD exhibit single nucleotide polymorphism (SNP) variants in the *MMP-9* gene, and elevated inflammation is associated with AMD pathogenesis (Fritsche et al., 2016; Kauppinen et al., 2016; Parks et al., 2004). Mutational variants in the inflammatory regulators, TIMP-3, TGFβ, TNF-α are also identified in human patients with AMD (Fritsche et al., 2016). We hypothesize that during photoreceptor regeneration in zebrafish, Mmp-9 functions late to resolve the acute inflammation stimulated by death of the photoreceptors, and, in the *mmp-9* mutants, there is prolonged inflammation that is selectively damaging to cones. The *mmp-9* mutants studied here may recapitulate elements of the pathologies that are characteristic of inflammatory photoreceptor diseases in humans, including AMD. Our study begins to shed light on the functional roles of Mmp-9 in the retina and a potentially important link between intrinsic retinal immunity, human photoreceptor dystrophies and photoreceptor regeneration.

Figure 1: Inflammation is induced following photoreceptor death and regulates reactive-proliferation.

(A) Time-course for the expression of inflammatory genes, from 8 to 168 hours post lesion (hpl). Unlesioned retinas served as controls. Expression levels are represented as fold change calculated using DDCT method. (B) Experimental paradigm for anti-inflammatory treatment with Dex and BrdU labeling. (C) BrdU immunostained cells (green) in controls (left) and Dex-treated animals (right) at 72 hpl. (D) Number of BrdU-labeled cells in controls (268 ± 36.1 cells; n=5) and Dex-treated animals (160.2 ± 20.02 cells; n=5) at 72 hpl; *p=0.0079. ONL- outer nuclear layer; INL- inner nuclear layer; GCL- ganglion cell layer. Scale bar equals 50μm.
Figure 2: Anti-inflammatory treatment suppresses photoreceptor regeneration. 

(A) Experimental paradigm of anti-inflammatory treatment. (B) Double labeled, regenerated photoreceptors using in situ hybridization for rods (rho) and cones (pde6c; red signal) and BrdU (green). The high magnification insets show the colocalization of the two labels. Control retinas are left; Dex-treated retinas are right. (C) Number of regenerated rod photoreceptors in control (42 ± 6.1 cells; n=7) and experimental retinas (25 ± 11.72 cells; n=7); *p=0.0047. (D) Number of regenerated cone photoreceptors in control (29.52 ± 4.1 cells; n=7) and Dex-treated animals (18.33 ± 5.71 cells; n=7). *p=0.0012. ONL- outer nuclear layer; INL- inner nuclear layer; GCL- ganglion cell layer. Scale bar equals 50μm.
Figure 3: Following a photolytic lesion, Müller glia and Müller glia-derived progenitors express mmp-9.

These experiments were performed using the transgenic line Tg[gfap:EGFP]mi2002, in which eGFP is expressed in Müller glia. (A) Triple labeling using in situ hybridization for mmp-9 (red signal) and immunostaining for BrdU for dividing cells (white; top row), combined with GFP immunostaining (green; bottom row). (B) Number of BrdU+ cells that express mmp-9 in unlesioned animals and lesioned animals at 24, 48, and 72 hpl. (C) Number of GFP+ Müller glia that also express mmp-9 expression at 24, 48, and 72 hpl. ONL- outer nuclear layer; INL- inner nuclear layer; GCL- ganglion cell layer. Scale bar equals 25 μm.
Figure 4: Mmp-9 is expressed and catalytically active following photoreceptor death. (A) Western blot of retinal proteins from unlesioned retinas (UL) and lesioned retinas at 16 hpl, 24 hpl, 48 hpl, 72 hpl, and 120 hpl, stained with anti-Mmp-9 and anti-actin (loading control) antibodies. (B) Densitometry of Mmp-9 protein. (C) Zymogram of Mmp-9 catalytic activity from unlesioned retinas (UL) and lesioned retinas at 16, 24, 48, 72 and 120hpl. Lanes in zymogram correspond to those in the Western blot. Purified human recombinant protein serves as a positive control. (D) Densitometry of Mmp-9 catalytic activity.
Figure 5: *mmp-9* is a component of the inflammatory response. 

(A) Experimental paradigm for the intraocular injections of TNF-α into unlesioned retinas and mRNA collection. (B) qRT-PCR for *mmp-9* expression in uninjected retinas (UI), retinas exposed to elution buffer only (EB), and retinas exposed to TNF-α. *p=0.0229. (C) qRT-PCR for *stat3* gene expression in uninjected retinas (UI), retinas exposed to elution buffer only (EB), and retinas exposed to TNF-α. *p=0.0344.
Figure 6: CRISPR mutants lack catalytically-active Mmp-9.
(A) Genomic structure of mmp-9 and the gRNA target sequence. (B) Sequence alignment for two indel mutations - 8 bp insertion and 23 bp deletion. Red underline indicates the sequence targeted by the 19 bp gRNA. (C) Western blot of retinal proteins from unlesioned retinas (UL wild-type; UL mmp-9+8 bp; UL mmp-9−23 bp) and lesioned retinas (wild-type; mmp-9+8 bp; mmp-9−23 bp) at 16, 24, and 48hpl stained with anti-Mmp-9 and anti-actin (loading control) antibodies. (D) Zymogram of Mmp-9 catalytic activity. Lanes in zymogram correspond to those in the Western blot. Purified human recombinant protein serves as a positive control.
Figure 7: Photolytic lesions in mmp-9 mutants results in the over production of injury-induced progenitors and regenerated photoreceptors. (A) BrdU-labeled cells (green) in wild-type and mmp-9 mutants. (B) Number of BrdU+ cells from wild-type (109 ± 19.66 cells; n=6) mutant retinas (142.3 ± 25.72 cells; n=9) at 72 hpl. *p = 0.0186. (C) BrdU-labeled cells (green) in wild-type and mutant retinas at 168 hpl. (D) Number of BrdU+ cells in the ONL of wild-type (48 ± 10.24 cells; n=8) and mutant retinas (71.71 ± 3.7 cells; n=8). *p=0.0001. (E) Double labeled, regenerated photoreceptors using in situ hybridization for rods (rho) and cones (pde6c; red signal) and BrdU (green) at 168hpl. (F) Number of regenerated cone photoreceptors in wild-type (31.42 ± 9.88 cell; n=8) and mutant retinas (43.83 ± 10.68 cells; n=8) at 168 hpl. *p=0.0301. (G) Number of regenerated rod photoreceptors in wild-type (14.88 ± 4.02 cells; n=8) and mutant retinas (26.04 ± 5.69 cells; n=8) at 168 hpl. *p=0.0005. ONL- outer nuclear layer; INL- inner nuclear layer; GCL- ganglion cell layer. Scale bars equal 50μm.
Fig 8. Mmp-9 regulates the maturation of regenerated photoreceptors.  
(A) Immunostaining for red-green double cones with ZPR-1 and rods with ZPR-3. Wild-type are in the top row; mutants are in the bottom row. Unlesioned retinas are left; lesioned retinas at 21 dpl are right.  
(B) Double labeled, regenerated photoreceptors at 21dpl using in situ hybridization for rods (rho) and cones (pde6c; red signal) and BrdU (green). Insets detail the morphology of regenerated photoreceptors in wild-type (left) and mutant retinas (right).  
(C) Number of regenerated cone photoreceptors (bottom) in wild-type (95.81 ± 18.49 cells; n=6) and mutant retinas (71.89 ± 20.37 cells; n=6) at 21 dpl. *p=0.0270. ONL- outer nuclear layer; INL- inner nuclear layer; GCL- ganglion cell layer. Scale bar equals 50μm.
Fig 9. Mmp-9 is required for the survival of regenerated cone photoreceptors.

(A) Wholemounts of wild-type (left) and mutant retinas (right) immunostained for ZO-1. Unlesioned retinas are top; lesioned retinas at 21dpl are bottom. (B) Number of regenerated cones from wild-type (599.11 ± 27.42 cones; n=5) and mutant retinas (436.09 ± 128.04 cones; n=5). *p=0.0238. (C) Western blot of retinas stained with antibodies against gnat-2 and actin at 7, 14, and 21 dpl. (D) Densitometry of gnat-2 labeling in the Western blot. A significant difference in gnat-2 levels were observed at 21 dpl. *p=.0014. Scale bar equals 10 μm.
Fig 10. Anti-inflammatory treatment rescues the maturation and number of regenerated cones in mutants at 21dpl.  
(A) Experimental paradigm for the photolytic lesions and Dexamethasone treatment used at 21 dpl.  
(B) Wholemounts of mutant retinas immunostained for ZO-1. Control retina is left; Dex-treated retina is right.  
(C) Number of regenerated cones in control (292.20 ± 158.11 cones; n=6) and Dex-treated retinas (522.79 ± 82.55 cones; n=6) at 21 dpl. *p=0.0010.  
(D) Immunostaining with ZPR-1 for red-green double cones in control (top) and Dex mutants (bottom) 21 dpl. Insets illustrate differences in the maturation and length of the photoreceptor outer segments.  
(E) Immunostaining for microglia using the 4C4 antibody in control (top) and Dex-treated retinas (bottom). Inserts illustrate ameboid (top) and ramified (bottom) microglia. Scale bars equal 10μm in panel A and 40μm in panels D and E.
Fig 11. Summary Diagram of cone regeneration (A) Müller glia respond to photoreceptor death by expressing mmp-9, undergoing interkinetic nuclear migration and a single asymmetric cell division that gives rise to a neuronal progenitor. (B) In wild-type animals, neuronal progenitors form a neurogenic cluster around the Müller glia (3 dpl), migrate to the ONL, and differentiate into cone photoreceptors (7 dpl) that then mature (21 dpl). (C) Anti-inflammatory treatment results in fewer Müller gli-derived progenitors and fewer regenerated photoreceptors. (D) In the absence of Mmp-9, there is overproduction of Müller glia-derived progenitors and regenerating photoreceptors. However, at 21dpl, cone maturation and survival are compromised. (E) In the absence of Mmp-9, anti-inflammatory treatment rescues the maturation and survival of cone photoreceptors. ONL- outer nuclear layer; INL- inner nuclear layer; GCL- ganglion cell layer.
