Abstract

The effect of disorder is investigated in granular superconductive materials with strong- and weak-links. The transition is controlled by the interplay of the tunneling $g$ and intragrain $g_{\text{intr}}$ conductances, which depend on the strength of the intergrain coupling. For $g \ll g_{\text{intr}}$, the transition first involves the grain boundary, while for $g \sim g_{\text{intr}}$, the transition occurs into the whole grain. The different intergrain couplings are considered by modeling the superconducting material as a disordered network of Josephson junctions. Numerical simulations show that on increasing the disorder, the resistive transition occurs for lower temperatures and the curve broadens. These features are enhanced in disordered superconductors with strong-links. The different behavior is further checked by estimating the average network resistance for weak- and strong-links in the framework of the effective medium approximation theory. These results may shed light on long standing puzzles such as: (i) enhancement of the superconducting transition temperature of many metals in the granular states; (ii) suppression of superconductivity in homogeneously disordered films compared to standard granular systems close to the metal–insulator transition; (iii) enhanced degradation of superconductivity by doping and impurities in strongly linked materials, such as magnesium diboride, compared to weakly linked superconductors, such as cuprates.

1. Introduction

The interplay of superconductivity and disorder has intrigued scientists for several decades [1]. Disorder is expected to enhance the electrical resistance, while superconductivity is associated with a zero-resistance state [2]. Bardeen, Cooper and Schrieffer explained the microscopic foundation of superconductivity in terms of pairing of electrons and the emergence of a many-body coherent macroscopic wavefunction [3]. Electron pairing defines a global order parameter $\Delta$ whose amplitude tends to zero with increasing temperature, current or magnetic field thus destroying the superconducting state. Anderson showed that weak disorder cannot lead to the destruction of the pair correlations. The transition temperature $T_c$ is insensitive to the elastic impurity scattering under the hypothesis that Coulomb interaction effects and mesoscopic fluctuations are negligible [4, 5]. However, experiments performed on thin films have demonstrated a transition from the superconducting to insulating state with increasing disorder or magnetic field. In sufficiently disordered metals, these effects become important and the Anderson theorem is violated [6–10].

Studies performed on homogeneously disordered conventional materials show, upon increasing disorder, suppression of the superconducting critical temperature $T_c$, enhancement of the spatial fluctuations in $\Delta$ and growth of the $\Delta/T_c$ ratio [11–13]. More recently, impurity effects have been investigated in unconventional d-wave superconductors, with the disorder causing pair breaking and suppression of $T_c$ [14–19]. The two-gap superconductivity is also affected by disorder.
Experiments on neutron-irradiated MgB$_2$ show that the two-gap feature is evident in the temperature range above 21 K, while single-gap superconductivity is well established as a bulk property, not associated with local disorder fluctuations, when $T_c$ is lowered to 11 and 8.7 K. The irradiation yields samples with an extremely homogeneous defect structure so that the superconducting transition remains extremely sharp even in the heavily irradiated samples [20, 21].

A still open issue in superconductivity is the enhancement of the critical transition temperature $T_c$ when some metals are in granular form rather than as a homogeneous bulk. It has been found that the enhancement is strongly dependent upon the intergrain coupling by varying the pressure [22, 23], with many experiments confirming this phenomenon [24–30]. Suppression of superconductivity in the vicinity of the metal–insulator transition has been observed in homogeneous superconductors such as amorphous Au$_x$Si$_{1−x}$ and Nb$_x$Si$_{1−x}$ [31]. Chemical substitutions and impurities in MgB$_2$ have resulted in superconductivity degradation and broadening of the $R(T)$ curve, pointing to an increasing effect of disorder in such a strongly linked class of superconductors [32–47].

Arrays of Josephson junctions with well controlled parameters are a very active field of research. As well as being of interest in their own right, they are also being used to model complex phenomena as a tool to investigate the effects of disorder in granular films [48–59].

This work is aimed at investigating the role of disorder in granular superconductors with different intergrain couplings, due to the presence of either strong- or weak-links. A parameter relevant to charge-carrier transport in such materials is the dimensionless tunneling conductance $g = G/(e^2/h)$, where $G$ is the average tunneling conductance between adjacent grains and $e^2/h$ the quantum conductance. Films with $g \gg 1$ can be modeled as arrays of resistively shunted Josephson junctions, whose state is controlled only by the value of the normal resistance rather than by the Josephson and Coulomb energies which are, respectively, defined as $E_J = (\pi/2)g\Delta$ and $E_C = e^2/C$, with $C$ the grain capacitance. The tunneling of normal electrons, which additionally takes place, results in the screening of the Coulomb energy, which reduces to the effective Coulomb energy $E_c = \Delta/(2g)$. By comparing the Josephson energy to the effective Coulomb energy, one can notice that $E_J$ is always larger than $E_c$ for $g \gg 1$. This condition ensures the onset of the superconducting state at low temperature. Experiments indeed show that samples with a normal state conductance larger than the quantum conductance (i.e. with $g \gg 1$) always become superconducting at low temperature.

A second parameter relevant to the understanding of the behavior of different granular materials is the intragrain conductance $g_{intr}$. For standard granular systems, the condition $g \ll g_{intr}$ holds. The intragrain region remains in the superconducting state, with the resistive transition occurring only at the grain boundaries. The condition $g \sim g_{intr}$ holds for tightly coupled grains, corresponding to homogeneously disordered materials having comparable values of the bulk and grain boundary conductances [32–34, 60–62].

The different role played by the tunneling and intragrain conductances is determined by the strength of the coupling between the grains. In this paper, the conditions $g \ll g_{intr}$ and $g \sim g_{intr}$ are considered in detail.

An array of Josephson junctions with different intergrain couplings and degrees of disorder is used to model the granular superconductor. The different contributions of $g$ and $g_{intr}$ are accounted for by a proper circuit representation of the grain and its boundary within the network. The study is carried out by means of a numerical simulation whose main steps are summarized in section 2. It is worth noting that the simulations reported in this work are carried out by the same numerical approach as in [55], where the different correlations shown by the current noise power spectra as a function of the intergrain coupling were investigated. The numerical results concerning the transition in weak- and strong-link networks as a function of the disorder are reported in section 3. The transition temperature $T_c$ is lowered and the shape of the transition curve becomes smoother by increasing the disorder. Importantly, it is found that the disorder affects more dramatically those networks with strong intergrain coupling. In section 4, the results are quantitatively accounted for by estimating the resistive changes in weakly and strongly linked networks according to the effective medium approximation.

2. Numerical model

As stated in section 1, the main purpose of this work is the investigation of the role of disorder in the resistive transition of granular superconductors with different intergrain couplings. The study will be carried out by adopting the numerical approach reported in [55], whose main steps are summarized here below.

The resistive transition is simulated by solving a system of Kirchhoff equations for a network of nonlinear resistors biased by direct current, as shown in figure 1(a). Two types of networks are considered for describing the different intergrain couplings. The first type is the weak-link network for simulating materials, whose transition occurs in two subsequent stages. First, at low temperatures, the weak-links and, then at slightly higher temperatures, the whole grain undergoes the transition reaching the normal state. The weak-link network is used to model the first stage of the transition occurring at the grain boundary, while the grain interior still remains superconducting. The strong-link network is used for modeling the transition involving the whole grain.

Grains are represented by a couple (triple) of nonlinear resistors for two-dimensional (three-dimensional) networks of Josephson junctions as shown respectively in figures 1(b) and (c). The nonlinear resistors provide a basis of independent components of the current density able to reproduce the current flowing through the grain in arbitrary directions. The nonlinear resistors have current–voltage characteristics as shown in figure 2 for underdamped (a), overdamped (b) and general (c) Josephson junctions. The Stewart–McCumber parameter $\beta_c = \tau_{RC}/\tau_J$, where $\tau_{RC}$ and $\tau_J$ are respectively the capacitance and the Josephson time constants, identifies the three types, namely $\beta_c \gg 1$ (a), $\beta_c \ll 1$ (b) and $\beta_c \sim 1$ (c). The dependence of
The critical current $I_{c,ij}$ and magnetic field $H_{c,ij}$ on temperature can be written in the simplified form as:

$$I_{c,ij}(T) = I_{co,ij} \left[ 1 - \left( \frac{T}{T_c} \right)^\gamma \right], \quad (1a)$$

$$H_{c,ij}(T) = H_{co,ij} \left[ 1 - \left( \frac{T}{T_c} \right)^\gamma \right], \quad (1b)$$

where $I_{co,ij}$ and $H_{co,ij}$ are respectively the low-temperature critical currents and magnetic fields and the exponent $\gamma$ ranges from approximately 1 to 2 depending on material properties.

The current flowing through each nonlinear resistor defines the state (superconductive, intermediate, normal) of the grain according to the current–voltage characteristics of the Josephson junction. As already stated, the disorder is introduced in the calculations by random distribution of the critical current. The anisotropy is neglected and the same size is assumed for the grains. The reason for these simplifying assumptions is that these two features may additionally alter the network topology with a strong effect on the transition. For small grain sizes in particular, the values of the critical current might be correlated in neighboring grains. Therefore, the correlation length of disorder should be taken into account by adopting a suitable spatial dependence of the critical current distribution. The critical current $I_{c,ij}(T)$ and the normal state resistance $R_{o,ij}$ are defined for each branch of the network. The intermediate state is characterized by the critical current $I_{c,ij}(T)$ and the voltage drop between 0 and $V_{c,ij}(T)$. The normal state, characterized by the resistance $R_{o,ij}$, is reached when the current $I$ crossing the Josephson junction exceeds $I_{c,ij}$. The disorder is introduced by taking the critical current $I_{co,ij}$ as a random variable distributed according to a Gaussian distribution with mean value $I_{co}$ and standard deviation $\sigma_c = \sqrt{\frac{\sum_{ij}(I_{co,ij} - I_{co})^2}{N}}$. Analogously, the disorder could be introduced by taking the critical field $H_{co,ij}$ as a random variable, if the transition were driven by an applied magnetic field $H$. The values of the resistances $R_{ij}$ between nodes $i$ and $j$ are taken as follows:

$$R_{ij} = 0 \quad \text{if} \quad V_{ij} \sim 0 \quad \text{(superconducting state)} \quad (2a)$$

$$R_{ij} = V_{ij} / I_{c,ij} \quad \text{if} \quad 0 < V_{ij} < V_{c,ij} \quad \text{(intermediate state)} \quad (2b)$$

$$R_{ij} = R_{o,ij} \quad \text{if} \quad V_{ij} > V_{c,ij} \quad \text{(normal state)} \quad (2c)$$

where $V_{ij}$ is the voltage drop between nodes $i$ and $j$. The current–voltage characteristic is used to find the value of the...
the standard deviation of the critical currents constant. The degree of disorder is varied by changing the value of

distinguished. In the superconducting, normal or intermediate state can be
different degrees of disorder at varying temperatures for

dimensional arrays as shown in figures 1(b) and (c).

Figure 3. Resistive transition of two-dimensional networks with
different degrees of disorder at varying temperatures for
weak-links (a) and strong-links (b). The bias current (or the magnetic field) is kept constant. The degree of disorder is varied by changing the value of the standard deviation of the critical currents $\sigma_{I_c}$ from 0 to 1 in steps of 0.1.

Calculations are performed iteratively. First, a tentative set of potential values is chosen for all the nodes. Then, the resistance values $R_{ij}$ are calculated by using the Josephson junction current–voltage characteristics for any resistor between nodes $i$ and $j$. Once the $R_{ij}$ are settled, the conductance matrix with entries $G_{ij} = 1/R_{ij}$ is defined and the new vector $W_1$ of the node potentials is calculated. The set of node potentials is introduced in the iterative routine and an updated vector $W_2$ is calculated. The iteration is repeated until the quantity $\varepsilon_n = |W_n - W_{n-1}|/|W_n|$ becomes smaller than a value $\varepsilon_{\text{min}}$ chosen to exit from the loop. The simulations are performed by varying $\varepsilon_{\text{min}}$ in the range $10^{-7} < \varepsilon_{\text{min}} < 10^{-11}$ to check that the value of $\varepsilon_{\text{min}}$ does not appreciably change the results. The network resistance $R$ is then obtained by $W_n(1)/I$, where $W_n(1)$ is the potential drop at the electrodes.

3. Numerical results

In this section, the results of the numerical simulations for different degrees of disorder are reported. It is shown that disorder affects weak- and strong-link networks to a different extent.

At the beginning the network is entirely in the superconducting state (this condition is guaranteed by taking $g \gg 1$). Subsequently, the transition is made to occur through one of these processes:

- The temperature is kept constant and the bias current (or the applied magnetic field) is varied. When the current $I_{ij}$ exceeds the critical current $I_{c,ij}$ (or the magnetic field exceeds the critical field $H_{c,ij}$), the superconductive grain evolves to the intermediate and, then, to the normal state.
- The bias current (or the magnetic field) is kept constant and the temperature is varied. A temperature increase causes a decrease of critical current $I_{c,ij}$ according to equation (1a) (or of critical field $H_{c,ij}$ according to equation (1b)) and, ultimately, causes the transition of the grain to the intermediate and, then, to the normal state.

As already stated, the disorder is modeled by assuming that the critical currents are a random variable distributed according to a Gaussian function with standard deviation $\sigma_{I_c}$. The spread of the distribution of the critical currents determines the slope of the transition curve [63]. The standard deviation $\sigma_{I_c} = 0$ corresponds to a fully ordered network, with all the Josephson junctions having the same critical current with the transition occurring simultaneously all through the network. When the disorder increases ($\sigma_{I_c}$ increases), the Josephson junctions have a wider spread of $I_{c,ij}$ and the network resistance changes more smoothly.

Figures 3(a) and (b) show the resistive transition of the network for different values of $\sigma_{I_c}$ for weak- and strong-link networks, respectively. The temperature increases while the external current $I$ is kept constant. As temperature increases, the critical current $I_{c,ij}$ decreases according to equation (1a). Links with $I_{c,ij}$ values smaller than $I_{ij}$ undergo the transition to the normal state. If $\sigma_{I_c}$ is small the resistive transition is steeper. In the limit of $\sigma_{I_c} = 0$ (no disorder in the network), the transition is vertical since all the Josephson junctions become
resistive for the same value of temperature. On the contrary, if \( \sigma_k \) is large the resistive transition broadens since the junctions become resistive at different temperatures. This effect occurs in both weak- and strong-link networks, but is enhanced in strong-link networks.

Figures 4(a) and (b) show the resistive transition when the bias current \( I \) increases at constant temperature, for different values of \( \sigma_k \) in weak- and strong-link networks, respectively. When the bias current \( I_{ij} \) exceeds \( I_{c,ij} \), the weak-links become resistive. The transition curves of figures 4(a) and (b) exhibit a behavior similar to those of figures 3(a) and (b). The disorder makes the resistive transition smoother, particularly in networks with strong-links.

4. Discussion

In this section, the results of the simulations will be discussed. One can observe that the average network resistance \( R \) is determined by the elementary nonlinear resistances \( R_{ij} \) between nodes \( i \) and \( j \). The values of \( R_{ij} \) depend on the external drive (current, magnetic field, temperature) and on the intrinsic properties of the junctions. The change in the resistance \( \Delta R_{ij} \) can be expressed in terms of the external drive variation as:

\[
\Delta R_{ij} = \frac{\partial R_{ij}}{\partial I} \Delta I + \frac{\partial R_{ij}}{\partial H} \Delta H + \frac{\partial R_{ij}}{\partial T} \Delta T. \tag{4}
\]

The three terms on the right-hand side of equation (4) can be written respectively as:

\[
\frac{\partial R_{ij}}{\partial I} = -\frac{\partial R_{ij}}{\partial I_c} \Delta I_c, \quad \tag{5a}
\]

\[
\frac{\partial R_{ij}}{\partial H} = -\frac{\partial R_{ij}}{\partial H_c} \Delta H_c, \quad \tag{5b}
\]

\[
\frac{\partial R_{ij}}{\partial T} = \left( \frac{\partial R_{ij}}{\partial I_c} \frac{\partial I_c}{\partial T} + \frac{\partial R_{ij}}{\partial H_c} \frac{\partial H_c}{\partial T} \right) \Delta T. \tag{5c}
\]

Equations (5a) and (5b) mean that the increase (decrease) of bias current or magnetic field acts as a decrease (increase) of critical current \( I_c \) or magnetic field \( H_c \). Equation (5c) means that the temperature affects \( R_{ij} \) mostly through a decrease in the critical current and magnetic field. By using equations (5a)–(5c), with the derivatives \( \partial I_c/\partial T \) and \( \partial H_c/\partial T \) in equation (5c) calculated by using equations (1a) and (1b), (4) can be rewritten as:

\[
\Delta R_{ij} = -\frac{\partial R_{ij}}{\partial I_c} \left( \Delta I_c + \frac{I_{co}}{T_c} \Delta T \right) - \frac{\partial R_{ij}}{\partial H_c} \left( \Delta H_c + \frac{H_{co}}{T_c} \Delta T \right). \tag{6}
\]

Equation (6) relates \( \Delta R_{ij} \) to the variation of critical current \( \Delta I_c \) or critical magnetic field \( \Delta H_c \). One can note that \( \Delta R_{ij} \) decreases when \( \Delta I_c \) or \( \Delta H_c \) increase due to the increased disorder in the array. Hence, since the network resistance \( R \) is proportional to terms varying as \( \Delta R_{ij} \), the slope of the resistive transition is smoother when \( \Delta I_c \) (\( \Delta H_c \)) increases for a given temperature increase \( \Delta T \), regardless of the coupling strength between grains.
the superconductive state before the transition of the layer. Let $N_{o,l}$ label the number of weak- or strong-links in the normal state and $N_{m,l} = N_{i,l} - N_{o,l}$ the number of weak- or strong-links in the intermediate state at a given stage of the transition of each layer. The resistance $R_l$ can be estimated as the parallel of the normal state resistors $R_{o,ij}$ and the intermediate state resistors $R_{m,ij}$ as:

$$R_l = \frac{R_{o,ij} R_{m,ij}}{N_{o,l} R_{m,ij} + N_{m,l} R_{o,ij}}$$  \hspace{1cm} (7)

The layer resistance $R_l$ depends on the ratio of the normal $N_{o,l}$ and mixed state $N_{m,l}$ resistances. For the strong-links, the voltage drop between two neighboring grains is calculated according to equation (3) and thus is larger than $V_{ij}$ (voltage drop across each weak-link). Therefore, since the condition given by equation (2b) is reached earlier, the denominator of

Figure 5. Scheme of two-dimensional networks when the first resistive layer is formed, for weak-links (a) and strong-links (b).

Figure 6. Resistive transition of a two-dimensional network with weak (blue) and strong (red) links as temperature increases. The standard deviation of the Gaussian distribution of the critical current $\sigma_{I_c}$ is equal to 0.2 for both curves. Zoom of the first step of the resistive transition in weak-link (b) and in strong-link (c) network.
equation (7) is larger in layers characterized by strong-links rather than weak-links for the same degree of disorder and bias current. This argument agrees with the fact that the resistive transition in strong-link networks occurs at temperatures lower than in weak-link networks.

Figure 6(a) shows the transition curves in weak- and strong-link networks with the same parameters. The slope is smaller for strong-link than for weak-link networks, consistent with the fact that the denominator of equation (7) is larger and thus ΔR ≈ Rl is smaller. Furthermore, one can notice by comparing figures 6(b) and (c) that the steps are higher for strong-links. This behavior has been confirmed by several runs of the transition simulations. Figures 8 and 9 show nine samples of the resistive transition for weak- and strong-links, respectively. One can clearly notice the different shape of the elementary steps. By implementing an automatic detection process of the step endpoints, the elementary derivatives can be estimated. Figure 10 shows the histograms of about 400 runs of the transition simulations. Figures 8 and 9 show nine samples of the resistive transition for weak- and strong-links. This behavior has been confirmed by several runs of the transition simulations.

The statistical analysis can be used for estimating an average step slopes for weak-link (a) and strong-link (b) networks. By comparing figures 6(b) and (c) that the steps are higher in the strong-link case should be correspondingly taken into account.

\[ R_{ij} = R_o \exp \left( \frac{\varepsilon_{ij}}{k_B T} + \frac{r_{ij}}{r_o} \right), \]  

(8)

where \( R_o = T k_B / (e^2 \gamma_{ij}^0) \), \( \gamma_{ij}^0 \) is a rate constant related to the electron-phonon interaction \( (k_B / e^2 \gamma_{ij}^0 \sim 1) \), \( r_{ij} \) is the distance between two sites, \( r_o \) is the scale over which the wavefunction decays outside the grain, \( \varepsilon_{ij} \) is the zero field activation energy given by \( \varepsilon_{ij} = \Delta_{ij}(T) + E_{c,ij} \), with \( E_{c,ij} = \beta e^2 r_{ij} / (\pi e_o d^2) \) the Coulomb energy and \( d \) the mean grain size. Therefore, equation (8) can be written as:

\[ R_{ij} = R_o \exp \left( \frac{\Delta_{ij}(T)}{k_B T} + \frac{r_{ij}}{r_o^*} \right), \]  

(9)

with \( 1/r_o^* = [1/r_o + \beta e^2/(2\pi e_o d^2 k_B T)] \). In equation (9), the resistance \( R_{ij} \) explicitly depends on the quantity \( r_{ij} \), which is the effective distance seen by an electron flowing from grain \( i \) to \( j \). The effective distance \( r_{ij} \) is different for electrons flowing either in weak- or strong-link networks. Such a difference can be estimated by taking into account that at constant current the voltage drop \( V_{ij} \) is proportional to \( r_{ij} \). The voltage drop for the strong-link case is given by equation (3). A reduction of a factor \( V_{ij}/(\sum V_{ij}^2)^{1/2} \) of the distance \( r_{ij} \) in comparison to the weak-link case should be correspondingly taken into account.

In the simplest case of isotropic spherical grains, \( V_{ij} \) is the same in any direction, thus the reduction factor is \( 1/\sqrt{2} \) or \( 1/\sqrt{3} \), respectively, for two- and three-dimensional networks.

By using the effective medium approximation [68], the average conductance \( G_{ema} \) of the network can be calculated as follows:

\[ \int dG_{ij} f(G_{ij}) \frac{G_{ema} - G_{ij}}{G_{ij} + (\sqrt{2} - 1)G_{ema}} = 0, \]  

(10)

Figure 7. Resistive transition of a two-dimensional network with weak (blue) and strong (red) links as the bias current increases. The standard deviation of the Gaussian distribution of the critical current \( \sigma_{c,i} \) is equal to 0.2 for both cases. Zoom of the first step of the resistive transition in weak-link (b) and strong-link (c) networks.
Figure 8. Resistive transitions of a two-dimensional network with weak-links. Elementary resistance steps can be clearly observed. These nine curves are typical samples used for obtaining the data plotted in the histogram shown in figure 10(a).

Figure 9. Same as in figure 8 but for strongly linked grains. The histogram is shown in figure 10(b).
Figure 10. Histograms of the slopes of the elementary steps for weak-link (a) and strong-link (b) networks. The elementary steps have been obtained by means of transition curves similar to those shown in figures 8 and 9.

where \( z \) is the number of bonds at each node of the network, \( G_{ij} = 1/R_{ij} \), and \( f(G_{ij}) \) is the probability distribution function of the elementary conductance values \( G_{ij} \). If the values \( G_{ij} \) are continuously distributed according to the uniform function \( f(G_{ij}) \propto 1/G_{ij} \), the average conductance is given by

\[
G_{ema} = G_2 \frac{\left( \frac{G_1}{G_2} \right)^{2z} - G_1}{(\xi - 1)[1 - \left( \frac{G_1}{G_2} \right)^{2z}]}.
\]

(11)

The average conductance \( G_{ema} \) varies as \( G_2 \) times a factor depending on the ratio \( G_1/G_2 \). The ratio \( G_1/G_2 \) is independent of the intergrain coupling, contrarily to \( G_2 \). Therefore one can observe that the average conductance \( G_{ema} \) increases as \( G_2 \) increases with the coupling strength. According to the presented model of the intergrain coupling, the value of the conductance \( G_2 \) in case of strong- and weak-link networks differs in the factor \( V_{ij}/(\sum V_{ij}^2)^{1/2} \). The average resistance \( R_{ema} = 1/G_{ema} \) is plotted in figure 11. It is worth noting that the resistance \( R_{ema} \) for the strong-link case is always smaller than for the weak-link case as expected from the simulations. The presented discussion could be useful to explain existing experimental observations in granular materials that are very hard to understand with conventional mechanisms [24–30].

5. Conclusions

The effect of disorder has been studied in superconductors with different strengths of intergrain coupling. The superconductor has been modeled as an array of Josephson junctions, numerically solved by using Kirchhoff equations. The analysis shows that, on varying the external drive (temperature, current, magnetic field), the resistive transition occurs for lower \( T_c \) and the \( R(T) \) curve broadens by increasing the disorder through a stepwise process. Importantly, it is found that the effect of disorder is more dramatic when the network simulates strongly rather than weakly coupled granular superconductors. The approach used and the results obtained in this work might add useful clues about the issue of the wide variability of critical temperature transition observed in real granular materials. It has indeed been observed that there is an increase in the critical temperature in compacted metallic powder compared to bulk samples of the same material. A strong anticorrelation between the enhancement of the critical temperature \( T_c \) and the value of metallic conductivity has been observed, indicating that a major role is played by the electron–electron interaction which acts by suppression of the superconductivity [22, 23].

Chemical substitutions for Mg or B have been attempted to vary the superconducting transition temperature of MgB\(_2\). Most of the substitutions have produced a depression of \( T_c \) and broadening of the \( R(T) \) curve, contrary to what is observed in cuprates in which replacement of La by Y raises \( T_c \) from 35 to 93 K and sharpens the transition curve. It has been suggested that the two-band nature of MgB\(_2\) can result in an unusual behavior of its resistivity and \( T_c \) as the material changes from the clean to dirty limit [32–34, 37, 38]. The suppression/enhancement of \( T_c \) is related to the competing effects of electron–electron and electron–phonon interaction, which in their turn depend on the size and radii of the compound and constituents. Intergrain and intragrain effects of disorder have been observed. Formation of magnesium or boron oxides results in poorly connected grains with an increase of intragrain resistivity and decrease of critical current density [35, 36]. At the same time, these oxides might migrate within the grains themselves, increasing intragrain resistivity and flux pinning. Other impurities such as silicon, carbon and copper greatly affect critical current, temperature and resistivity [39–46]. Degradation of the critical temperature and broadening of the \( R(T)/R_c \) curve have been also observed in MgB\(_2\) film by exposure to water [47]. The general feature of these experiments is that degradation of superconductivity seems to be related to the enhanced role of electron–electron interaction and impurity scattering in homogeneous metallic-like superconductors compared to the standard granular ones, i.e. that class of materials whose intergranular conductance \( g \) is much smaller than the intragranular conductance \( g_{intr} \). The dominant effect of the electron–electron interaction is taken into account in the present model by introducing suitable circuit coupling among grains.
Figure 11. Average network resistance $R_{ema}$ calculated according to the effective medium approach for $z = 3$ (a), $z = 4$ (b), $z = 5$ (c), $z = 6$ (d). Red curves refer to strongly coupled grains. Blue curves refer to weakly coupled grains. One can observe that the average resistance is smaller for strongly coupled networks for all the $z$ values.
