Thermoelectric properties of aluminum compound-doped \( \alpha \)-SiC ceramics

Chul-Hoon PAI
Department of Nano-Bioengineering, Incheon National University, Incheon 406-772, Korea

The effects of aluminum compound additive on the thermoelectric properties of \( \alpha \)-SiC ceramics were studied. Porous SiC ceramics with 50–60% relative density were fabricated by sintering the pressed \( \alpha \)-SiC powder compacts with AlN and/or Al\(_4\)C\(_3\) at 2150°C for 3 h in Ar atmosphere. The sintered bodies were analyzed by means of XRD, SEM, and TEM. The lattice parameter measurements revealed incorporation of a certain amount of added Al and/or N into the SiC lattice. 6H to 4H reverse phase transformation occurred during sintering. The Seebeck coefficient, electrical conductivity and thermal conductivity were measured at 550–950°C in Ar and/or vacuum atmosphere. The kind of additives and the amount of addition had significant effects on the thermoelectric properties. The thermoelectric figure of merit of aluminum compound-doped SiC increased with increasing temperature and was lower than that of n-type SiC. On the whole, AlN-doped SiC had higher figure of merit than Al\(_4\)C\(_3\)-doped SiC.

1. Introduction
Thermoelectric energy conversion utilizing nuclear heat sources has been employed for several decades to generate power for deep space probes. The development of thermoelectric materials has recently been resurrected once again for applications such as high-temperature thermoelectric power generation. For effective utilization of solar heat, nuclear energy and waste heat from industries, materials possessing high thermoelectric energy conversion efficiency and usable at high temperatures are intensely required.

The goodness of a semiconductor in thermoelectric conversion is given by its so-called figure of merit, \( Z \), and is expressed by \( Z = \frac{\sigma \alpha^2}{k} \), where \( \sigma \) is the electrical conductivity, \( \alpha \) is the Seebeck coefficient and \( k \) is the thermal conductivity. For developing thermoelectric materials, a large number of work have been concentrated on increasing the figure of merit, \( Z \) by increasing the electrical conductivity and Seebeck coefficient with reduction of thermal conductivity.

Generally, the thermoelectric materials can be classified into three classes by the temperature which indicates the maximum value of figure of merit; the low (r.t.-100°C), middle (200–600°C) and high (above 700°C) temperature materials. Compound semiconductors, such as Bi\(_2\)Te\(_3\), PbTe, and their solid solutions, have already been commercially applied to both refrigeration and power generation.\(^1\) However, the materials so far developed are easily oxidized, decomposed, or melt above 1000°C and are not suitable for high-temperature applications.

Silicon carbide is now being considered for high-temperature structural applications because of its extreme hardness, excellent thermal and mechanical properties, and high thermal shock resistance. Furthermore, silicon carbide is considered to be a potentially useful material for high-temperature electronic devices as its band gap is large compared to silicon and the p-type and/or n-type conduction can be controlled by impurity doping.

A commercial \( \alpha \)-SiC powder (Cerac Inc., purity; 99% up, average particle size; \( \sim 0.4 \mu \)m) and aluminum compound additives (0–5 mass %) were mixed by ball-milling(Y-TZP balls/alumina jar) process. AlN (Cerac Inc., purity; 99%, –200 mesh) and/or Al\(_4\)C\(_3\) (Cerac Inc., purity; 99%, –325 mesh) were employed as additives. Porous SiC ceramics with 50–60% relative density were fabricated by sintering the pressed powder mixture compacts (compaction pressure; 200 kg/cm\(^2\)) at 2150°C for 3 h in Ar atmosphere. The relative density was calculated from a measured apparent density. X-ray diffraction (XRD) analysis was performed to examine the phases present and precise lattice parameters of the sintered body were measured using CuK\(_\alpha\) radiation with Ni filter and high-purity silicon as an internal standard. Scanning electron microscope (SEM) and Transmission electron microscope (TEM) observations were carried out to examine the microstructure of sintered bodies.

Key-words: \( \alpha \)-SiC, AlN, Al\(_4\)C\(_3\), Electrical conductivity, Seebeck coefficient, Thermal conductivity, Figure of merit

2.2 Measurements of thermoelectric property

Four grooves were put on a rectangular specimen. Heads of the two Pt-Pt·13%Rh thermocouples were embedded in the drilled holes at the two ends of a specimen and they were held in place with Pt wires placed along the grooves. The electrical conductivity and thermoelectric power were measured simultaneously for the same specimen at 550–950°C in Ar atmosphere. Electrical conductivity was measured using a d.c. four-probe technique. Ohm’s law was always checked by changing the current value. The average voltage drop obtained from forward/reverse current directions was used to calculate the conductivity. For thermoelectromotive force measurements, a temperature gradient in the specimen was generated by flowing cool air in an alumina protection tube placed near the one end of the specimen. The temperature difference between the two ends was controlled to be 5 to 10 K by varying the flow rate of air. Plots of thermoelectromotive force vs. temperature difference gave rise to a straight line in all cases, and the Seebeck coefficient was calculated from its slope.

Thermal diffusivity and specific heat capacity were measured by a usual laser flash method. One side of a disc specimen cut out from a sintered body was pasted with glassy carbon for effective absorption of the laser energy. A thermocouple was fixed on the rear side to measure the temperature rise after the flash of laser pulse. Thermal diffusivity and specific heat capacity were measured separately at 550–950°C in vacuum. Calibration of the apparatus was carried out using a sapphire single crystal before each measurement. The thermal conductivity was calculated from thermal diffusivity, specific heat capacity, and density.

3. Results and discussion

3.1 Thermoelectric properties of aluminum compound-doped α-SiC

Microstructure variation with varying the amount of additive is expressed in terms of the relative density and porosity as shown in Table 1. It can be seen that the change of relative density and porosity was little occurred in the case of AlN doping and occurred slightly in the case of Al4C3 doping. The SEM observations (Fig. 1) revealed that the grain size increases slightly in the case of AlN doping and little changed in the case of Al4C3 doping. It might be affected by aluminum and/or nitrogen incorporated during the sintering process. Silicon Carbide is produced commercially with >95% theoretical density when boron(B) and carbon(C) are added. Prochazka5) has suggested that B promotes solid-state sintering by segregating selectively in grain boundaries and excess B produces a B-rich phase at the grain boundaries. However, in this study, mass transfer for grain growth would become suppressed by the strain due to the doped aluminum and/or nitrogen.

Table 2. Lattice Parameters of SiC Sintered at 2150°C for 3 h in Ar Atmosphere

| Sample No. | Lattice Parameter (nm) | a | c |
|------------|------------------------|---|---|
| N          | 0.30821                | 1.51237 |
| AN1        | 0.30832                | 1.51245 |
| AN2        | 0.30834                | 1.51248 |
| AN3        | 0.30843                | 1.51259 |
| AN4        | 0.30847                | 1.51257 |

Table 1. Relative Densities and Porosities for the Specimens

| Sample No. | Additive | Content (mass %) | Temp. (°C) | Time (h) | Atmosphere | R.D. (%) | Porosity (%) |
|------------|----------|------------------|------------|----------|------------|----------|--------------|
| N          | —        | —                | —          | —        | —          | 52.12    | 23.45        |
| AN1        | —        | 0.5              | —          | —        | —          | 50.18    | 23.06        |

| AC1        | AlN      | 0.5              | 1250       | 3        | Ar         | 59.15    | 17.17        |
| AC2        | AlN      | 1                | 1250       | 3        | Ar         | 59.59    | 17.13        |
| AC3        | AlN      | 3                | 1250       | 3        | Ar         | 58.07    | 18.14        |
| AC4        | AlN      | 5                | 1250       | 3        | Ar         | 55.27    | 20.21        |
addition, which was expected since the covalent radius of Al (0.118 nm) is larger than that of Si (0.111 nm) in the case of Al₄C₃ doping. And this might be due to the effect of N (0.075 nm) replaced Si and/or C (0.077 nm) in the case of AlN doping. Slake et al.⁷) reported that the N is incorporated into the C at low N concentrations of 10¹⁶ cm⁻³ and may also replace some Si at a level of >2 × 10²⁰ cm⁻³.

Figure 4 shows the temperature dependence of electrical conductivity. It can be seen that electrical conductivity for all doped specimens are higher than that of undoped specimen, which must be due to the change in carrier concentration. It can be also seen in Fig. 4 that Al₄C₃-doped specimens have generally higher electrical conductivity than AlN-doped specimens, except for the result of 5 mass % addition and this might be due to the difference in carrier concentration, phase composition, and microstructure.

In the case of AlN doping [Fig. 4(a)], it appeared that electrical conductivity increased with increasing the amount of AlN addition. This might be due to the effect of 6H to 4H reverse phase transformation. The hole mobility of 4H-SiC is higher than that of 6H-SiC.⁸) In the case of SiC, cubic β-SiC stabilized by doped-N and hexagonal α-SiC stabilized by doped-B and -Al.⁹)–¹⁰) Specially, 6H to 4H reverse phase transformation occurs by doped-Al at high temperature.¹¹)–¹²) In this study, it can be seen in Fig. 5 that the peak of 4H phase increases and that of 6H phase decreases with increasing the amount of AlN addition. And electrical conductivity of 5 mass % AlN-doped specimen was higher, it might be explained from the view point of the microstructure. That is, 5 mass % added specimen has the best grain-to-grain connectivity among three kinds of specimens [Figs. 1(b)–1(d)]. This result is consistent with the previous report¹³) that electrical conductivity of n-type β-SiC increases with increasing compaction pressure, that is, the grain-to-grain connectivity of β-SiC became larger as increasing compaction pressure without noticeable change of relative density and average grain size. Better grain-to-grain connectivity must have played a role partly in increasing conductivity.

On the other hand, in the case of Al₄C₃ doping, it appeared that electrical conductivity of 1 mass % added specimen was higher and decreased with increasing the amount of Al₄C₃ addition. This might be due the difference in carrier concentration and microstructure. A polycrystalline material is composed of small crystallites joined together by grain boundaries. The grain boundary is a complex structure, usually consisting of a few atomic layers of disordered atoms. Seto¹³) reported that the electrical transport properties of polycrystalline silicon films are governed by carrier trapping at the grain boundary. That is, the trapping states are capable of trapping carries and thereby immobilizing them. This reduces the number of free carriers available for electrical conduction. Consequently, in this study, electrical conductivity of Al₄C₃-doped specimens decreased with increasing the amount of excess Al₄C₃ segregated in grain boundaries. It can be also seen in Fig. 6 that the effect of 6H to 4H reverse phase transformation was smaller than the case of AlN doping.

### 3.2 Thermoelectric energy conversion by porous SiC with aluminum compound addition

For the purpose of materials design for thermoelectric energy conversion, it is convenient to define a figure of merit (Z) for an individual material as $Z = \frac{\alpha^2}{\kappa}$. That is, to increase thermoelectric energy conversion efficiency, a material having high electrical conductivity, large Seebeck coefficient, and low thermal conductivity is need. Thermal conductivity of a sintered body is generally influenced by its density and purity.¹⁴) It can be seen in
Fig. 7 that thermal conductivity of porous SiC ceramics with AlN and/or Al4C3 addition is lower than about 1/10 of the values for dense SiC ceramics.14)

Figure 8 shows the temperature dependence of a figure of merit calculated using the data shown in Figs. 2, 4, and 6. The figure of merit increased with increasing temperature. However, Al4C3-doped specimen has somewhat lower figure of merit than AlN-doped specimen, since the former has very small Seebeck coefficient in comparison with the latter. On the whole, the effect of Seebeck coefficient was larger than that of electrical conductivity.

Hence it can be stated that the thermoelectric properties of p-type SiC ceramics could be further improved by appropriate doping and a precise control of microstructure.
4. Conclusions

The results of this study are summarized as follows:

(1) A certain amounts of added AlN and/or Al4C3 were incorporated into the SiC lattice. The Seebeck coefficients for all doped specimens were positive (p-type semiconducting) and larger than that of undoped specimen, which might be caused by microstructure homogeneity. Electrical conductivity for all doped specimens was also higher than that of undoped specimen caused by carrier concentration.

(2) The Seebeck coefficients deceased with increasing the amount of additives addition caused by carrier concentration. The specimens doped AlN were apparently larger Seebeck coefficient, which might be due to the stacking fault density and carrier concentration.

(3) In the case of AlN doping, it appeared that electrical conductivity increased with increasing the amount of AlN addition, which might be mainly due to the effect of 6H to 4H reverse phase transformation.

(4) In the case of Al4C3 doping, it appeared that electrical conductivity was slightly higher than that of AlN-doped caused by carrier concentration. Electrical conductivity of 3 mass % added specimen was higher and the excess addition had harmful influence upon electrical conductivity, which might be due the difference in carrier concentration and microstructure.

(5) Thermal conductivity of aluminum compound-doped SiC was lower than about 1/10 of the values for dense SiC ceramics.

(6) The figure of merit for aluminum compound-doped SiC increased with increasing temperature. On the whole, AlN-doped SiC had higher figure of merit than Al4C3-doped SiC, since the effect of Seebeck coefficient was larger than that of electrical conductivity.
