Optimal Resource Allocation in Ground Wireless Networks Supporting Unmanned Aerial Vehicle Transmissions

Yulin Hu, Senior Member, IEEE, Guodong Sun, Guohua Zhang, M. Cenk Gursoy, Senior Member, IEEE, and Anke Schmeink, Senior Member, IEEE

Abstract—We consider a fully-loaded ground wireless network supporting unmanned aerial vehicle (UAV) transmission services. To enable the overload transmissions to a ground user (GU) and a UAV, two transmission schemes are employed, namely non-orthogonal multiple access (NOMA) and relaying, depending on whether or not the GU and UAV are served simultaneously. Under the assumption of the system operating with infinite blocklength (IBL) codes, the IBL throughputs of both the GU and the UAV are derived under the two schemes. More importantly, we also consider the scenario in which data packets are transmitted via finite blocklength (FBL) codes, i.e., data transmission to both the UAV and the GU is performed under low-latency and high reliability constraints. In this setting, the FBL throughputs are characterized again considering the two schemes of NOMA and relaying. Following the IBL and FBL throughput characterizations, optimal resource allocation designs are subsequently proposed to maximize the UAV throughput while guaranteeing the throughput of the cellular user. Moreover, we prove that the relaying scheme is able to provide transmission service to the GU while improving the GU’s performance, and that the relaying scheme potentially offers a higher throughput to the UAV in the FBL regime than in the IBL regime. On the other hand, the NOMA scheme provides a higher UAV throughput (than relaying) by slightly sacrificing the GU’s performance.

Index Terms—finite blocklength coding, NOMA, relaying, resource allocation, UAV

I. INTRODUCTION

The past few years have witnessed a tremendous increase in the deployment and use of unmanned aerial vehicles (UAVs) in both commercial and civilian applications, such as for aerial surveillance, traffic control, photography, package delivery, and so on [1]–[4]. Hence, the ground wireless networks are expected to not only serve ground users (GU) but also provide ubiquitous communication services for the UAVs, i.e., support the communication between the UAVs and their users or controllers [5], [6]. Consequently, ground networks supporting UAV communications have relatively more workload.

Non-orthogonal multiple access (NOMA) and relaying are known as promising techniques enhancing the performance of overloaded networks. By applying the successive interference cancellation (SIC) technique, NOMA enables two (or more) users to transmit data packets in a single time-frequency resource block by exploiting differences in channel conditions [7]. Authors in [8] address the impact of user pairing on the NOMA system. In [9], the sum-throughput achieved with NOMA is investigated. Recently, for a UAV-assisted NOMA network where the UAV serves as an access-point, the outage probability of GUs [10] and the UAV trajectory designs [11] are addressed, respectively. In addition, cooperative relaying has been also shown as an efficient way to improve the system performance [12], [13] by letting one user (with a better link to the access point) perform as a relay to assist the other weak-link user(s). For a UAV network, it has proposed in [12] to apply the UAV as a relay and study the throughput maximization of the system. In addition, experiments on such UAV-relaying ad hoc networks are conducted in [13]. From a resource allocation perspective, the authors in [14] maximize the precision of a UAV-aided recommendation system by optimally allocating the resource of computing, delay, and traffic resource. The allocation of tours of targets to vehicles is investigated in [15] for a multi-UAV system to minimize the sum of the flying distances of UAVs. The frequency allocation problem is addressed in [16] for a UAV-assisted D2D network. However, fundamental characterizations and optimal designs for the network of a UAV in pair with a GU are yet to be identified under both the NOMA and relaying schemes.

Moreover, all the above studies are conducted under the assumption of transmitting arbitrarily reliably at Shannon’s capacity. In other words, these results are only accurate for the network with significantly long blocklengths. Note that both UAV and GU can be deployed to support latency-critical applications with high reliability requirements, e.g., remote control. Due to these critical latency and reliability requirements, data transmissions are realized by codes with short blocklengths, i.e., the networks operate in the so-called finite blocklength (FBL) regime in which the transmissions are no longer arbitrarily reliable [17]. To tackle this problem, FBL information theoretic bounds are developed in [18] for an additive Gaussian noise (AWGN) in a single hop transmission. In addition, the model has been extended to quasi-static fading channels [19], [20], cooperative relaying networks [21] and NOMA networks [22], [23]. More recently, a joint blocklength and UAV location optimization is studied in [24] for a FBL network where the UAV is considered as a flying base-station/relay. In addition, the authors in [25] consider a UAV
network including a ground access point (AP) and UAV-users, and maximize the available range of the AP to support FBL communications for these UAV-users. However, note that with a high probability of having a line-of-sight (LoS) link, a UAV-user generally has strong channels from the ground AP and to GUs. On the one hand, significant channel quality difference generally exists between the channels from AP to the UAV-user and to a GU, which motivates one to apply NOMA between the two users experiencing the channel difference. On the other hand, as the link from the UAV-user to the GU is likely to be strong, this indicates a potential performance improvement (in both IBL and FBL regimes) for the GU when the UAV-user performs as a relay to assist the data transmission to the GU. Hence, it is essential to study and optimize the performance of such pair of users. To the best of our knowledge, both the IBL and the FBL performances of a UAV-user paired with a GU under either the NOMA scheme or the relaying scheme have yet to be characterized and maximized via optimal resource allocation.

In this work, we consider a ground wireless network supporting UAV transmissions, where a UAV and a GU are served under either the NOMA or relaying scheme. The throughputs of UAV and GU are characterized in the IBL regime and the FBL regime, addressing the latency-non-sensitive applications and low-latency high-reliability applications, respectively. Following these characterizations, we propose optimal resource allocations to maximize the UAV throughput while guaranteeing the GU’s transmission quality. The contributions of this paper can be further detailed as follows:

- The throughputs of UAV and GU are characterized in both the IBL and FBL regimes.
- Following the throughput characterizations, optimal resource allocation designs are determined under the NOMA and relaying schemes, when the objective is to maximize the UAV throughput while guaranteeing the GU’s transmission quality. The designs are addressed in the IBL regime and the FBL regime, respectively.
- We further address the feasibility of the considered optimization problems. In particular, we prove that the relaying is able to create a win-win situation, i.e., provides transmission service to the UAV while improving the GU’s performance. Moreover, we prove that the relaying scheme potentially offers a higher throughput to the UAV in the FBL regime than in the IBL regime, as in the FBL regime it likely requires less resources to guarantee the GU’s transmission quality and therefore allocates more resources to the UAV.

The remainder of the paper is organized as follows: In Section II, we describe the system model, review the FBL performance metrics and provide the problem statement. In Section III, throughputs of the considered network are characterized under the NOMA and relaying schemes, respectively. Subsequently in Section IV, we analyze the optimal resource allocation strategies, which maximize the UAV throughput while guaranteeing the GU’s transmission quality. The feasibility of the resource allocation problems are further discussed in Section V. We provide our simulation results in Section VI and finally conclude the paper in Section VII.

II. PRELIMINARIES

In this section, we first briefly describe the considered scenario of a UAV connected ground wireless network. Subsequently, we introduce the channel model representing the wireless link characteristics. Finally, we review the FBL performance model of a single link transmission in comparison to the IBL performance model.

A. System Description

We consider a ground wireless network with an AP serving its own GUs. At the same time, a UAV is additionally required to be served beside the GUs. In particular, due to the resource (e.g., frequency, power) limitation in the network, the service to the UAV is provided by using the existing resources i.e., without incurring additional costs in terms of more frequency bands or increased transmit power in the network. To satisfy this condition, one practical approach is to select a GU and use the frequency band allocated to this GU to serve both the GU and the UAV jointly, as shown in Fig. 1. At the same time, the selected GU’s transmission quality (with respect to throughput and reliability) should be guaranteed (in comparison to being solely served) when applying such joint transmission scheme.

![Fig. 1. An example of the considered network, where the AP-UAV link has the line of sight (LoS), the AP-GU link has no LoS (NLoS), and the UAV-GU link is possible to have the LoS (PLoS).](image)

We assume that the system operates in a time-slotted fashion where time is divided into frames with a length of $M$ symbols. The gains of the channels from the AP to the UAV, from the AP to the GU, and from the UAV to the GU are denoted by $G_1$, $G_2$, and $G_3$, respectively. Then, the channel gains are modeled by $G_i = z_i10^{-L_i}$, $i = 1, 2, 3$, where $L_i$, $i = 1, 2, 3$, represent the path losses (in dB) in these links. In addition, $z_i$, $i = 1, 2, 3$, denote the gains due to the random channel fading. In particular, we assume that channels experience block-fading, i.e., $z_i$, $i = 1, 2, 3$, are constant within a frame and vary from one frame to the next.

1\footnote{Generally, if we select the GU which has a poor channel to the AP, its transmission performance via the AP-GU link (being solely served before paring with the UAV) is low. Hence a similar transmission performance of this GU is relatively easier to be guaranteed by applying joint transmission schemes to the GU-UAV pair.}
B. IBL Regime vs. FBL Regime

First of all, it should be pointed out that for a practical communication system, the blocklength is definitely not infinite. Hence, when we study the performance of such a system in the IBL regime, this only indicates that the impact of the limited length of coding blocks is ignored in the analysis. In particular, the analysis in the IBL regime follows the assumption which is only true when the blocklength is infinitely long: a packet is assumed to be decoded with arbitrarily small error probability given that the coding rate is lower than the Shannon capacity.

In an AWGN channel, the Shannon capacity, which quantifies throughput in the IBL regime, is given in bits/symbol by

\[ C = \log_2(1 + \gamma), \tag{1} \]

where \( \gamma \) is the signal to noise ratio (SNR) or signal to interference plus noise ratio (SINR) at the receiver.

Under the more practical assumption that the coding blocklength is finite, i.e., the system operates in the FBL regime, the decoding error may occur even when the transmission coding rate is set to be lower than the Shannon capacity. In an AWGN channel, the normal approximation of the coding rate \( r \) (in bits per channel use) of transmission is derived in [26]. Later on, this approximation is improved to be more tighter in [26], where the third-order term of the normal approximation is derived. In particular, with blocklength \( m \), block error probability \( \epsilon \), and SNR (or SINR) \( \gamma \), the coding rate \( r \) is given by [26]

\[ r = R(m, \gamma, \epsilon) = \log_2(1 + \gamma) - \log_2 e \frac{\gamma (\gamma + 2)}{(\gamma + 1)^2 m} Q^{-1}(\epsilon) + \frac{\log m}{m} + o(1) \tag{2} \]

where \( Q^{-1}(x) \) is the inverse Q-function and the Q-function is given by \( Q(x) = \int_{x}^{\infty} \frac{1}{\sqrt{2\pi}} e^{-t^2/2} dt \). On the other hand, when the coding rate is fixed as \( r \), the error probability of the transmission is given by

\[ \epsilon = P(m, \gamma, r) = Q \left( \frac{\log_2(1 + \gamma) - r - \frac{\log m}{m} - o(1)}{\frac{\gamma (\gamma + 2)}{(\gamma + 1)^2 m}} \right). \tag{3} \]

According to the characterizations in [18], the achievable coding/data rate in the FBL regime increases in the blocklength. In particular, there exists a performance gap between the Shannon capacity and FBL achievable rate. This performance gap in a single-hop system is numerically shown in Fig. 2. The figure illustrates that the gap is more significant for short blocklengths, and the FBL performance degrades significantly as the blocklength is decreased.

C. Problem Statements

Our main focus in this work is to investigate the performance of the UAV-connected wireless system. We propose to apply two transmission schemes and evaluate the throughput to the UAV. In particular, we address the following fundamental problems: When comparing NOMA and relaying, which one is more preferred under which condition? How to provide an optimal throughput to the UAV (under both the NOMA and relaying schemes) while guaranteeing the GU’s transmission quality by applying optimal resource allocation? What are the performance differences in the considered network under the IBL and FBL assumptions? How different the optimal resource allocation solutions are in the FBL regime in comparison to the IBL regime?

III. Transmission Schemes and Throughput Characterizations

In this section, we present the NOMA and relaying schemes and characterize the corresponding throughputs in the links to the UAV and the GU. The characterizations of the two schemes are provided in both the IBL and FBL regimes.

A. IBL Regime

If the AP serves only its GU and not the UAV, the throughput of the GU is given by

\[ \mu^\text{IBL}_G = M \log_2 \left( 1 + \frac{p_0 G_2}{\sigma^2} \right). \tag{4} \]

If, on the other hand, the UAV is served jointly with the GU, the system behavior changes. In the following, we address the throughputs (including both the UAV and GU) considering the NOMA and relaying schemes, respectively.

1) NOMA: In the NOMA scheme, AP transmits two signals \( x_{\text{uav}} \) and \( x_{\text{gu}} \) within the same coding length of \( M \) symbols via the same frequency band to the UAV and GU simultaneously. Denote by \( p_1 \) and \( p_2 \) the per symbol transmit power of the two transmitted signals, i.e., \( p_1 = E(\|x_{\text{uav}}\|^2)/M \) and \( p_2 = E(\|x_{\text{gu}}\|^2)/M \). Note that the AP-UAV link is with high probability to have line of sight (LoS) while the link from the AP to the selected GU (that is paired with the UAV) can experience more severe fading (e.g., due to blockages and multipath fading). In other words, the quality of the AP-UAV link is higher than that of the AP-GU link, i.e., \( G_1 > G_2 \). Hence, without loss of generality, in the NOMA process we assume \( p_2 > p_1 \) and let the UAV apply SIC to cancel the inference of \( x_{\text{gu}} \).

![Fig. 2. Performance gap between the IBL and FBL regimes in a single-hop system with a static channel. The FBL (achievable) rate is calculated according to (2) while the target error probability is set as $10^{-4}$.](image-url)
The received signal at the UAV is given by
\[ y_1 = \sqrt{p_1G_1}x_{\text{uav}} + \sqrt{p_2G_1}x_{\text{gu}} + n, \] (5)
where \( n \) denotes the Gaussian noise with power \( \sigma^2 \). Note that the interference signal needs to be successfully cancelled, which requires \( \frac{p_2G_1}{p_1G_1 + \sigma^2} > \frac{p_2G_2}{p_1G_2 + \sigma^2} \). Moreover, the IBL throughput of the UAV under the NOMA scheme is given by
\[ \mu_{\text{IBL}}^{\text{NOMA}} = M \log_2 \left( 1 + \frac{p_1G_1}{\sigma^2} \right). \] (6)

On the other hand, the signal received by the GU is
\[ y_2 = \sqrt{p_1G_2}x_{\text{uav}} + \sqrt{p_2G_2}x_{\text{gu}} + n. \] (7)
Decoding the signal \( x_{\text{gu}} \) while treating \( x_{\text{uav}} \) as interference, the GU’s throughput is given by
\[ \mu_{\text{IBL}}^{\text{GU}} = M \log_2 \left( 1 + \frac{p_2G_2}{p_1G_2 + \sigma^2} \right). \] (8)

2) Relaying: Under the relaying scheme, the UAV becomes both a data receiver and a relay to forward the GU’s data packet. In this scheme, the total length \( M \) of a frame is further divided into two phases with lengths \( m_1 \) and \( m_2 \), satisfying \( m_1 + m_2 = M \). In the first phase, the AP transmits a large data packet (containing the messages intended for both the UAV and GU) to the UAV. If the UAV decodes the large data packet correctly and recovers both messages, it forwards the GU’s data in the second phase. Thus, the IBL throughput of the GU under the relaying scheme is
\[ \mu_{\text{IBL}}^{\text{R,2}} = m_2 \log_2 \left( 1 + \frac{p_2G_2}{\sigma^2} \right). \] (9)
Note that the large data transmitted to the UAV includes both the UAV’s data and the GU’s data. Hence, under the relaying scheme the throughput via the link to the UAV is given by \( m_1 \log_2 \left( 1 + \frac{p_1G_1}{\sigma^2} \right) \), which equals the sum of the UAV’s IBL throughput \( \mu_{\text{IBL}}^{\text{R,1}} \) and the GU’s throughput \( \mu_{\text{IBL}}^{\text{R,2}} \). Therefore, the IBL throughput of the UAV can be expressed as
\[ \mu_{\text{IBL}}^{\text{R}} = m_1 \log_2 \left( 1 + \frac{p_1G_1}{\sigma^2} \right) - \mu_{\text{IBL}}^{\text{R,2}}. \] (10)

B. FBL Regime

Note that in the FBL regime, transmissions are not arbitrarily reliable anymore. We denote by \( \nu_1 \) and \( \nu_2 \) the reliability requirements of the transmissions to the UAV and the GU, respectively. When only the GU is served by the BS, the total error probability is exactly the decoding error probability at the GU. According to (3), when the AP only serves the GU, the FBL throughput is given by
\[ \mu_{\text{FBL}}^{\text{GU}} = M \cdot \mathcal{R} \left( M, \frac{p_2G_1}{\sigma^2}, \nu_2 \right) \cdot (1 - \nu_2), \] (11)
In the following, we discuss the FBL throughput performance of the NOMA and relaying schemes while guaranteeing the GU’s reliability requirement.

1) NOMA: In the NOMA scheme, the UE decodes the received signal given in (7) by treating \( x_{\text{uav}} \) as interference. Hence, the GU’s the throughput is given by
\[ \mu_{\text{FBL}}^{\text{GU}} = M \cdot \mathcal{R} \left( M, \frac{p_2G_1}{p_1G_1 + \sigma^2}, \nu_2 \right) \] (12)
where \( r_2 = \mathcal{R} \left( M, \frac{p_2G_2}{p_1G_2 + \sigma^2}, \nu_2 \right) \) is the coding rate of the data to the GU.

On the other hand, the decoding process at the UAV consists of two steps, i.e., UAV first applies SIC and subsequently decodes its own signal. Hence, both the SIC errors and the decoding errors of the UAV’s own signal contribute to the total error probability. Denote by \( \epsilon_{\text{SIC}} \) and \( \epsilon_{\text{NU,1}} \) the error probabilities of SIC and decoding the UAV’s data packet at the UAV. Then, the total error probability of the transmission to the UAV is given by \( 1 - (1 - \epsilon_{\text{SIC}})(1 - \epsilon_{\text{NU,1}}) \). Note that the error probability of this SIC process is given by
\[ \epsilon_{\text{SIC}} = \mathcal{P} \left( M, \frac{p_2G_1}{p_1G_1 + \sigma^2}, r_2 \right). \] (13)
Hence, to satisfy the reliability requirement, i.e., \( 1 - (1 - \epsilon_{\text{SIC}})(1 - \epsilon_{\text{NU,1}}) = \nu_1 \), the target error probability of the UAV’s data transmission is required to be set to \( \epsilon_{\text{FBL}}(\nu_1) = 1 - \frac{1 - \nu_1}{1 - \epsilon_{\text{SIC}}} \).

After successfully applying the SIC, the UAV subsequently decodes its own data. The FBL throughput of the UAV in the NOMA scheme is given by
\[ \mu_{\text{FBL}}^{\text{NOMA}} = M \cdot \mathcal{R} \left( M, \frac{p_2G_1}{p_1G_1 + \sigma^2}, \nu_1 \right) \] (14)
where \( r_1 = \mathcal{R} \left( M, \frac{p_2G_2}{p_1G_2 + \sigma^2}, \epsilon_{\text{NU,1}} \right) \) is the coding rate of the data packet to the UAV.

2) Relaying: Under the relaying scheme, the AP first transmits a large data packet in first phase to the UAV. The decoding error probability of this transmission is exactly the total error probability of the UAV’s data transmission, i.e., it is required to satisfy the reliability constraint \( \nu_1 \). Hence, the FBL throughput of the transmission to the UAV, including the data for both UAV and GU, is given by
\[ \mu_{\text{FBL}}^{\text{R}} = m_1 \cdot \mathcal{R} \left( m_1, \frac{p_1G_1}{\sigma^2}, \nu_1 \right) \cdot (1 - \nu_1). \] (15)
As long as the UAV’s decoding process is successful, the UAV forwards the GU’s data packet in the second phase. Denote by \( \epsilon_{\text{R,2}} \) the target decoding error probability at the GU. According to the total reliability constraint of GU \( \nu_2 \), it holds that \( \nu_2 = 1 - (1 - \nu_1)(1 - \epsilon_{\text{R,2}}) \). Hence, we have \( \epsilon_{\text{R,2}} = 1 - \frac{1 - \nu_2}{1 - \nu_1} \). Then, the GU’s FBL throughput is given by
\[
\mu_{\text{FBL}}^{\text{R,2}} = m_2 \mathcal{R} \left( m_2, \frac{p_2G_3}{\sigma^2}, \epsilon_{\text{R,2}} \right) \cdot (1 - \nu_1)(1 - \epsilon_{\text{R,2}}) = m_2 \mathcal{R} \left( m_2, \frac{p_2G_3}{\sigma^2}, \epsilon_{\text{R,2}} \right) \cdot (1 - \nu_2).
\] (16)
\[ ^{\text{It should be pointed out that the decoding error probability is set as large as possible to ensure the loosest constraint so that the maximum throughput could be obtained.}} \]
Finally, the UAV’s throughput can be obtained as

\[ \mu_{R,1}^{\text{FBL}} = m_1 \cdot R \left( m_1, \frac{p_1 G_1}{\sigma^2}, \nu_1 \right) \cdot (1 - \nu_1) - \mu_{R,2}^{\text{FBL}}. \] (17)

So far, we have characterized the throughput performance of the considered NOMA and relaying schemes in both the IBL and FBL regimes. Following these characterizations, we provide the corresponding optimal resource allocation designs in the next section.

IV. RESOURCE ALLOCATION FOR MAXIMAL UAV THROUGHPUT

In this section, by applying resource allocation, we investigate the optimal UAV throughput under both the NOMA and relaying schemes. Our objective is to maximize the throughput without using any additional resources (e.g., in terms of transmission blocklength and transmit power), while guaranteeing the GU’s transmission requirements including throughput and reliability (in the FBL case). In particular, we seek to guarantee the GU a weighted throughput level of \( \gamma \), where \( \mu_0 \) is the GU throughput if the UAV is not jointly served, and \( \beta > 0 \) is the minimum rate coefficient, which is a key factor that indicates the level of service guarantee. For example, \( \beta < 1 \) indicates that only partial throughput can be provided to the GU in comparison to the case in which the UAV is not served. On the other hand, \( \beta > 1 \) represents the scenario in which GU performance is required to be better than the non-UAV-connected case.

A. UAV Throughput Maximization under the NOMA Scheme

According to (6) and (14), the UAV throughput in the NOMA scheme can be maximized by choosing an optimal \( p_1 \). The general optimization problem of the NOMA scheme (in both the IBL and FBL regimes) is formulated as:

\[
\begin{align*}
\text{max} \quad & \mu_{N,1} \\
\text{s.t.} \quad & \mu_{N,2} \geq \beta \mu_0, \\
& p_1 + p_2 \leq p_0, \quad p_1, p_2 \in R^+. \quad (18a)
\end{align*}
\]

We have the following proposition for the above problem

Proposition 1. The optimal throughput offered to the UAV is obtained when the inequality constraints in (18b) and (18c) are satisfied with equality.

Proof: We prove the result by contradiction. Regarding the sum power constraint in (18c), we first assume that there exists an optimal solution \((p_1^*, p_2^*)\) satisfying the constraints with strict inequality, i.e., \( p_0 - p_1^* - p_2^* = \rho > 0 \). Hence the optimal throughput offered to the UAV and the GU are \( \mu_{\text{UAV}} \) and \( \mu_{\text{GU}} \). On the other hand, we could further allocate the power left to UAV \( p_1^* \) and GU \( p_2^* \) in proportion to \( p_1^* \) and \( p_2^* \). Thus the data rate to the GU is \( c_{gu} = \log_2 \left( 1 + \frac{p_1 G_1}{\rho_1 + p_1 G_2} \right) \).

Since

\[ \frac{(p_1^* + p_2^*) G_2}{(p_1^* + p_2^*) G_2^2 + \sigma^2} > \frac{(p_1^* + p_2^*) G_2 + \frac{\sigma^2}{\rho_1 + p_1^* G_1}}{(p_1^* + p_2^*) G_2 + \frac{\sigma^2}{\rho_1 + p_1^* G_1}}, \]

the GU could get more throughput. At the same time, the data rate of UAV is \( c_{\text{UAV}} = \log_2 \left( 1 + \frac{p_1 G_1}{\sigma^2} \right) \), and thus the throughput to the UAV is also higher. Therefore, the assumption that \((p_1^*, p_2^*)\) is the optimal solution to the problem is violated. i.e., the optimal power allocation satisfies (18c) with equality. Similarly, the strict equality of (18b) and guaranteeing constraint can be proved.

According to Proposition 1, the original optimization problem for the NOMA scheme is equivalent to

\[
\begin{align*}
\text{max} \quad & \mu_{N,1} \\
\text{s.t.} \quad & \mu_{N,2} = \beta \mu_0, \\
& p_1 + p_2 \leq p_0, \quad p_1, p_2 \in R^+. \quad (19a)
\end{align*}
\]

We have the following solve the optimization problem given in (19) in the IBL and FBL regimes, respectively.

1) UAV Throughput Maximization under the NOMA Scheme in the IBL Regime: According to (9), constraint (19b) is equivalent to the following equation

\[ \gamma_{IBL}^{gu} \triangleq \frac{p_2 G_2}{p_1 G_2 + \sigma^2} = 2 \frac{\mu_{IBL}}{\mu_0} + 1, \] (20)

where \( \gamma_{IBL}^{gu} \) represents the received SINR for the GU when decoding its own data packet. Clearly, \( \gamma_{IBL}^{gu} \) is a constant for a given \( \beta \).

According to (19c), \( p_2 = p_0 - p_1 \) holds. Substituting this into (20), the optimal solution (of the NOMA scheme in the IBL regime) to Problems (18) and (19) is given by

\[ p_{N,1}^{IBL} = p_0 - \gamma_{IBL}^{gu} G_0 + \gamma_{IBL}^{gu} \frac{\sigma^2}{2 (1 + \gamma_{IBL}^{gu})}. \] (21)

By inserting \( p_1 = \mu_{IBL}^{IBL} \) and \( p_2 = p_0 - p_1 \) into (6), the optimal throughput of the UAV is obtained.

2) UAV Throughput Maximization under the NOMA Scheme in the FBL Regime: Similarly, in the FBL regime, to guarantee constraint (19b), the coding rate of the data packet to the GU should satisfy \( r_2 = \frac{\beta \mu_0}{M (1-r_2)} \). Hence, according to (12), the SINR at the GU should satisfy

\[ \gamma_{IBL}^{FBL} = \frac{1}{M (1-r_2) (p_0 G_2 + \sigma^2)}. \] (22)

By substituting \( p_2 = p_0 - p_1 \), the optimal power allocation is obtained as

\[ p_{N,1}^{FBL} = p_0 - \gamma_{IBL}^{FBL} G_0 + \gamma_{IBL}^{FBL} \frac{\sigma^2}{2 (1 + \gamma_{IBL}^{FBL})}. \] (23)

Hence, we have \( p_2 = p_0 - p_{N,1}^{FBL} \). Then, the optimal throughput of the UAV and the corresponding throughput of GU in the FBL regime can be immediately calculated according to (14) and (12).

B. UAV Throughput Maximization under the Relaying Scheme

In the relaying scheme, the total frame length of \( M \) symbols is separated into two phases with lengths of \( m_1 \) and \( m_2 \). Hence, to maximize the throughput of the UAV in the IBL regime given in (10) and in the FBL regime given in (17), the optimal transmit powers \( p_1 \) and \( p_2 \) as well as the optimal blocklengths \( m_1 \) and \( m_2 \) should be determined. The optimiza-
Hence, the above problem is equivalent to

\[ \max_{p_1, m_1} \mu_{R, 1} \]
\[ \text{s.t.} \quad \mu_{R, 1} \geq 0, \]
\[ \mu_{R, 2} = \beta \mu_0, \]
\[ m_1 p_1 + m_2 p_2 \leq M p_0, \quad p_1, p_2 \in R^+, \]
\[ m_1 + m_2 \leq M, \quad m_1, m_2 \in R^+, \]

where the constraint (24b) indicates that the throughput of the first phase should be higher than the second phase. Similar to the discussion in Proposition 1, the inequalities in (24c), (24d) and (24e) should be satisfied with equality to maximize \( \mu_{R, 1} \). Hence, the above problem is equivalent to

\[ \max_{p_1, m_1} \mu_{R, 1} \]
\[ \text{s.t.} \quad \mu_{R, 1} \geq 0, \]
\[ \mu_{R, 2} = \beta \mu_0, \]
\[ m_1 p_1 + m_2 p_2 = M p_0, \quad p_1, p_2 \in R^+, \]
\[ m_1 + m_2 = M, \quad m_1, m_2 \in R^+. \]

In the following, we solve the problem in both the IBL and FBL regimes.

1) UAV Throughput Maximization under the Relaying Scheme in the IBL Regime: We first propose the following key proposition to solve Problem (25) in the IBL regime.

**Proposition 2.** Problem (25) is convex in the IBL regime.

**Proof:** Note that \( \mu_{R, 2} = \beta \mu_0^{IBL} \). Hence, we have \( p_2 = \frac{\sigma^2}{G_3} \left( \frac{\mu_0^{IBL}}{2} - 1 \right) \). To guarantee (25d) and (25e), we should have

\[ p_1 = \left( M p_0 - (M - m_1) \left( \frac{2 \mu_0^{IBL}}{G_3} - 1 \right) \sigma^2 \right) / m_1. \]

Substituting (26) into (10), the throughput can be expressed as

\[ \mu_{R, 1}^{IBL} = m_1 \log_2 \left( 1 + \frac{M p_0 - (M - m_1) \left( \frac{2 \mu_0^{IBL}}{G_3} - 1 \right) \sigma^2}{m_1 \sigma^2} \right) G_1 \]

\[ - \beta \mu_0, \]

(27)

in terms of the single variable \( m_1 \). Hence, the proposition is proved if \( \mu_{R, 1}^{IBL} \) in (27) is concave in \( m_1 \). We show this concavity as follows.

First, we introduce an auxiliary function \( t \) with respect to \( m_1 \)

\[ t = \left( M p_0 - (M - m_1) \left( \frac{2 \mu_0^{IBL}}{G_3} - 1 \right) \sigma^2 \right) G_1 \]

\[ \frac{\sigma^2}{G_3}. \]

We further obtain the first and second order derivatives of \( t(m_1) \):

\[ \frac{\partial t}{\partial m_1} = \frac{G_1}{G_3} \left( 2 \frac{\mu_0^{IBL}}{G_3} - 1 - \frac{\beta \mu_0 \log_2(2)}{M - m_1} \right). \]

(29)

By introducing \( g = 2 \frac{\mu_0^{IBL}}{G_3} \geq 0 \), we have

\[ \frac{\partial t}{\partial m_1} = \frac{G_1}{G_3} \left( (1 - g \log_2 e) 2^g - 1 \right) \leq 0. \]

(30)

In addition, we have

\[ \frac{\partial^2 t}{\partial m_1^2} = -\frac{G_1}{G_3} \beta^2 M^2 \log_2(2) 2^g \frac{2 \mu_0^{IBL}}{G_3} \leq 0. \]

(31)

Then, the objective in (27) can be expressed as

\[ \mu_{R, 1}^{IBL} = m_1 \log_2 \left( 1 + \frac{t}{m_1} \right) - \beta \mu_0. \]

(32)

We can obtain the second order derivative of \( \mu_{R, 1}^{IBL} \) with respect to \( m_1 \) as

\[ \frac{\partial^2 \mu_{R, 1}^{IBL}}{\partial m_1^2} = \frac{m_1^3 \frac{\partial^2 t}{\partial m_1^2} - 2 m_1^2 \frac{\partial t}{\partial m_1} + 2 m_1 \frac{\partial^2 t}{\partial m_1} + 2 t (\frac{\partial^2 t}{\partial m_1^2})^2}{\log_2(2)(m_1 + t)} \]

(33)

where \( m_1 \) is by definition positive. According to (30) and (31), \( \frac{\partial^2 \mu_{R, 1}^{IBL}}{\partial m_1^2} \leq 0 \) holds.

According to Proposition 2, Problem (25) can be solved efficiently in the IBL regime.

2) UAV Throughput Maximization under the Relaying Scheme in the FBL Regime: Note that the \( R \) function in (3) is not concave. Hence, the objective function in Problem (25) is not concave in the FBL regime, i.e., Problem (25) is not convex. In the following, we solve the problem in the FBL regime by utilizing the monotonic property.

**Proposition 3.** The objective of Problem (25) is a monotonic function with respect to two variables \( p_1 \) and \( m_1 \), if the blocklength and reliability requirements are within a range of practical interest, i.e., \( m \geq 84 \) (which is the smallest blocklength in LTE-A) and \( c < 10^{-3} \).

**Proof:** Clearly the proposition holds if it is shown that \( r = R(m_1, \gamma_1, \epsilon_{uav}) \) is monotonically increasing in both \( \gamma_1 \) and \( m_1 \). The first derivatives of \( r \) with respect to \( \gamma_1 \) and \( m_1 \) are given by

\[ \frac{\partial r}{\partial \gamma_1} = \frac{(\gamma_1 + 1) \sqrt{\gamma_1^2 + 2 \gamma_1} - Q^{-1}(\epsilon_{uav})/m_1}{(1 + \gamma_1)^2 \sqrt{\gamma_1^2 + 2 \gamma_1}} \log_2 e, \]

(34)

\[ \frac{\partial r}{\partial m_1} = \frac{1}{2} Q^{-1}(\epsilon_{uav}) \sqrt{\gamma_1 (\gamma_1 + 2) / (\gamma_1 + 1)^2 m_1^2} \log_2 e + \frac{1 - \log_2 m_1}{m_1^2}. \]

(35)

We assume that in our scenario the SNR is higher than 0 dB, i.e., \( \gamma > 1 \) and the practical value of \( m_1 > 84 \) and \( Q^{-1}(\epsilon_{uav}) \) is in \((2.3263, 5.9978)\). For (35), if \( (\gamma_1 + 1) \sqrt{\gamma_1^2 + 2 \gamma_1} > 1 \) and \( Q^{-1}(\epsilon_{uav})/m_1 < 1 \) hold, then \( \frac{\partial r}{\partial \gamma_1} > 0 \). For (35), if we denote \( c = \frac{1}{2} \log_2 e \cdot Q^{-1}(\epsilon_{uav}) \sqrt{\gamma_1 (\gamma_1 + 2) / (\gamma_1 + 1)^2 m_1^2} \) for short, the minimum of \( \frac{\partial r}{\partial m_1} \) is obtained at \( m_1 = (\frac{1}{2} c)^2 \). For \( m_1 \in (m_1', M) \), \( m_1' \) is increasing in \( m_1 \). For \( m_1 > 84 \), to guarantee \( \frac{\partial r}{\partial m_1} > 0 \), \( c > 0.3743 \) is required. As for the practical values mentioned above, \( \frac{\partial r}{\partial m_1} > 0 \).  

We thus have \( \frac{\partial r}{\partial m_1} > 0 \).
As the objective function is monotonic increasing with respect to both variables $m_1$ and $p_1$, the problem can be solved by applying the framework of monotonic optimization \[27\], resulting in a global optimum.

V. FEASIBILITY ANALYSIS ON GUARANTEERING THE WEIGHTED THROUGHPUT OF THE GU

So far, we have characterized the IBL and FBL throughputs under both the NOMA and relaying schemes and provided corresponding optimal resource allocation designs while guaranteeing the weighted throughput of the GU, i.e., guaranteeing $\beta\mu_0$. In this section, we provide a feasibility discussion on $\beta$ for both schemes.

We start with the NOMA scheme and introduce the following proposition

**Proposition 4.** Under the NOMA scheme, the feasible range of $\beta$ values is $\beta \in [0, 1]$ in both the IBL regime and FBL regime.

*Proof:* Recall that for both the IBL and FBL regimes, under the NOMA scheme the GU decodes the received signal based on the SINR $\gamma_2 = p_2G_2/p_1G_1 + \sigma^2$. Under the power constraint $p_0 = p_1 + p_2$, we have $\max \gamma_2 = p_2G_2/p_1G_1$, which is exactly the SNR of the GU when it is being solely served by the network. In such case, $p_1 = 0$ and $p_2 = p_0$, which indicates that allocating zero power to the UAV only guarantees $\beta = 1$. Hence, the proposition is verified. 

Proposition 4 indicates that when additionally serving the UAV (with a positive throughput) under the NOMA scheme, part of the GU’s throughput is sacrificed. On the other hand, the sum throughput of the UAV and the GU is boosted, as the channel from the AP to the UAV is much stronger than the one to the GU.

Next, we discuss the relaying scheme and have the following proposition

**Proposition 5.** For the relaying scheme, the feasible value of $\beta$ is possible to be higher than 1. In such case, a win-win situation is created, i.e., the UAV is additionally served while the GU’s performance is improved.

*Proof:* We first show that $\beta \geq 1$ possibly holds under the relaying scheme by considering the following example. We consider a relaying scheme with $m_1 = m_2 = M/2$. Note that the IBL throughput to the UAV is non-negative, i.e., $\frac{M}{2}\log_2(1 + \frac{p_1G_1}{\sigma^2}) - \beta M\log_2(1 + \frac{p_0G_2}{\sigma^2}) \geq 0$. Hence, we have

$$\beta > 1$$

$$\Leftrightarrow \log_2(1 + \frac{p_1G_1}{\sigma^2}) - \log_2\left(1 + \frac{p_0G_2}{\sigma^2}\right)^2 > 0$$

$$\Leftrightarrow \left(1 + \frac{p_1G_1}{\sigma^2}\right) > \left(1 + \frac{p_0G_2}{\sigma^2}\right)^2.$$ 

Note that the channel from the AP to the UAV is generally LoS and the link from the AP to the selected GU (in pair with the UAV) is generally weak, i.e., it is more likely that $G_1 \gg G_2$. Hence, there exist feasible $p_1$ and $p_0$, which satisfy $\left(1 + \frac{p_1G_1}{\sigma^2}\right) > \left(1 + \frac{p_0G_2}{\sigma^2}\right)^2$.

The possibility of $\beta \geq 1$ can be also proved in the IBL regime based on the following Lemma 1 which provides that if $\beta > 1$ is guaranteed in the IBL regime, it also possibly holds in the FBL regime.

**Lemma 1.** In the relaying scheme with given $\beta$, $m_1$ and $m_2$, under certain conditions guaranteeing GU’s transmission quality in the FBL regime requires less transmit power $p_2$ to GU than guaranteeing it in the IBL regime.

*Proof:* We prove Lemma 1 by discussing the special case in which we have $\beta = 1$, $m_1 = m_2 = M/2 = m$ and the reliability constraint of UAV is much lower than the GU, i.e., $\nu_1 \ll \nu_2$. In addition, we consider a reliable transmission scenario where the SNRs of all links are higher than 1.

In the IBL regime, according to (37), the throughput requirement of the GU is $\log_2(t_2) = 2\log_2(t_0)$, where we have defined $t_0 = 1 + \frac{p_0G_2}{\sigma^2}$. Then, the IBL throughput of the UAV is obtained by

$$c = \log_2(t_1) - \log_2(t_2) = \log_2\frac{t_1}{t_2},$$

where $t_1 = 1 + \frac{p_1G_1}{\sigma^2}$ and $t_2 = 1 + \frac{p_2G_2}{\sigma^2}$.

In the FBL regime, the GU’s throughput requirement is given in (37). Noting that $\nu_1 \ll \nu_2$, we have $\epsilon_{R,2} = \nu_2 - \nu_1 + \nu_1\epsilon_{R,2} \equiv \nu_2$, i.e., $Q^{-1}(\nu_2) \approx Q^{-1}(\epsilon_{R,2})$. We define $A = Q^{-1}(\nu_2)\log_2 e \approx Q^{-1}(\epsilon_{R,2})\log_2 e$ and $B = \log_2\frac{m_1}{m_2} = \log_2\frac{p_1}{p_2}$. In addition, we denote $t'_2 = 1 + \frac{p_1G_1}{\sigma^2}$ and $t'_1 = 1 + \frac{p_2G_3}{\sigma^2}$ where $p'_1$ and $p'_2$ are the power allocation results in the FBL regime. Then, the GU’s throughput requirement given in (37) can be represented by

$$\log_2 t'_2 - A \sqrt{1 - \frac{1}{(t'_2)^2}} - B = 2 \left(\log_2 t_0 - A \sqrt{1 - \frac{1}{t_0^2}} - B\right).$$

Hence, we have

$$\log_2 t'_2 = 2\log_2 t_0 - A \left(2\sqrt{1 - \frac{1}{t_0^2}} - \sqrt{1 - \frac{1}{t_0^2}} - B\right).$$

Noting that SNRs are higher than 1, we have both $t_0 > 2$ and $t'_2 > 2$ hold. Therefore $2\sqrt{1 - \frac{1}{t_0^2}} - \sqrt{1 - \frac{1}{t_0^2}} \geq 0$ by transforming into $3 \geq 4 - \frac{1}{t_0^2}$, which is obviously valid. Thus $\log_2 t'_2 < \log_2 t_2$ holds, which is equivalent to $p'_2 < p_2$. This indicates that more resources could be allocated for the first hop, i.e., the serving quality of UAV is better than that calculated in the IBL regime.

VI. SIMULATION RESULTS AND DISCUSSION

In this section, we provide our simulation results. We first validate our analytical model and subsequently evaluate the IBL and FBL performances of the considered network. The simulation results are conducted under the following parameter setups. First, we consider a 3-dimensional topology where the AP is deployed at point $(0, 0, 20)$, while the UAV and GU positions are set to $(100, 0, 100)$ and $(700, 0, 0)$. In addition,
the total transmit power is $p_0 = 1W = 30dBm$ while the noise power is $\sigma^2 = -80dBm$. Moreover, we set the frame length to $M = 400$ symbols. Finally, for the analysis in the FBL regime, the target error probabilities of the transmissions to the UAV and the GU are set to $\nu_1 = 10^{-4}$ and $\nu_2 = 10^{-3}$, respectively. Moreover, noting that the AP-GU link, the AP-UAV link, and the UAV-GU link have different probabilities of LoS, in the simulation we consider the following path loss exponents, which are potentially different for the three links with different probabilities of LoS. In particular, we adopted the setups from \cite{28} and set $\alpha_1 = 2$ for the AP-UA V link (with LoS) and $\alpha_2 = 3.5$ for the AP-GU link (without LoS). Moreover, following the model in \cite{29}, we have the following path loss exponent for the UAV-GU link: $\alpha_3 = a_1 \cdot P(\theta) + b_1$, where $P(\theta) = \frac{1}{1 + e^{-\theta}}$, $a_1$ is the probability of the LoS between UAV and GU, as introduced in \cite{30}. In addition, we set $a_1 = -1.5$, $a_2 = 2$, $a_3 = 9.61$, and $b_2 = 0.16$, according to the rural area setup in \cite{31}.

### A. Validations

In this subsection, we validate our analytical model via simulation and numerical results that depict the instantaneous performances within a single frame.

We start with Fig. 3(a) to show the impact of power allocation on the UAV throughput. The figure has two parts, i.e., Fig. 3(a) and Fig. 3(b). In particular, Fig. 3(a) provides the all the feasible values of IBL throughput of the UAV under the NOMA scheme, i.e., the objective in Problem (18), while satisfying the inequality constraints (18b) and (18c). In addition, the optimal solution to Problem (18) obtained via exhaustive search is also provided in the figure as a red point. The two cut-surfaces crossing the optimal solution point actually represent the equality cases of (18b) and (18c). Clearly, Fig. 3(a) shows that under the scenario that $\beta = 0.5$, the optimal solution satisfies (18b) and (18c) with equality. Moreover, a set of corresponding results are provided in Fig. 3(b) where different values of $\beta$ are considered. Again, it is observed that the optimal solutions are exactly the crossing points where the power constraint and the GU’s throughput constraint hold with equality, verifying Proposition 1.

Next, we consider the relaying scheme in the IBL regime. In Fig. 4, we show the relationship among the IBL throughput of UAV, blocklength $m_1$ and transmit power $p_1$, when $\beta = 1.0$. Note that only the feasible vaules of the UAV’s throughput are visible, i.e. the blocklength and power allocation must satisfy the constraints in (24). Clearly, it is observed that the UAV throughput in the IBL regime is concave in $m_1$ and $P_1$, confirming the characterization in Proposition 2.

In addition, in Fig. 4(a) we investigate the relationship between the throughput of the UAV with the blocklength $m_1$,
blocklength longer than that required at the maximum point is allocated. In parallel, the impact of transmit power $p_1$ on the throughput of the UAV is given in Fig. 5(b) for different values of the blocklength $m_1$. It is observed that the UAV throughput is monotonically increasing in the transmit power allocated to the first hop within the feasible set. In other words, Fig. 5 confirms Proposition 3 that the UAV throughput under the relaying schemes is a monotonic function with respect to $p_1$ and $m_1$ within the corresponding feasible sets.

Moreover, Fig. 6 studies the throughput of the UAV while comparing the NOMA and the relaying schemes in both the IBL and FBL regimes. In the simulation, we vary the minimum rate coefficient $\beta$ from 0.5 to 2. The throughput of the UAV under the NOMA scheme is depicted using circle markers, while the performance under the relaying scheme is shown with a plus marker. The solid lines represent the performance in the IBL regime and the dashed line is indicating the performance in the FBL regime.

It is evident in Fig. 6 that the feasible ranges of the minimum rate coefficient are different in the two schemes. In particular, the NOMA curves drop rapidly as $\beta$ gets close to 1. This confirms Proposition 4 that the NOMA scheme only serves the UAV with $\beta \in [0, 1]$ in both the IBL and FBL regimes. On the other hand, the relaying scheme could offer more throughput ($\beta > 1$) to the GU and serve the UAV simultaneously, i.e., offer a win-win strategy, which matches our characterization in Proposition 5. In addition, we could observe from Fig. 6 that under the NOMA scheme, the throughput of the UAV in the FBL regime is smaller than the throughput in the IBL regime. More interestingly, the FBL throughput under the relaying scheme is higher than the IBL throughput when $\beta$ is higher than 0.6. This verifies Proposition 1 that under the relaying scheme, it is possible that less resource is required in the FBL regime (than in the IBL regime) to guarantee the GU’s transmission quality, i.e., more resources could be spent for the UAV.

Next, we show the impact of $m_1$ on the throughput of the UAV in Fig. 7, where results in both the IBL and FBL regimes are provided. The difference between Fig. 7 and Fig. 5(a) is that the transmit power $p_1$ in Fig. 7 is optimally chosen. It is observed that the optimal blocklength of the first hop in the FBL regime is shorter than the one in the IBL regime.
which again confirms Lemma 1. Moreover, this blocklength difference between the two regimes is getting smaller as the total frame length increases.

To discuss the applicability of the model under the proposed schemes, we place another GU at (400, 0, 0), which is closer to the AP than the setup in Fig. 6 where the single GU is located at (700, 0, 0). The throughput results are illustrated in Fig. 8. In contrast to Fig. 6, the win-win region (\( \beta > 1 \) and UAV throughput is positive) of relaying is much smaller in Fig. 8. On the other hand, for \( \beta < 0.99 \), the NOMA scheme outperforms the relaying scheme in both the IBL and FBL regimes. In other words, when the UAV is paired with the GU which has a good channel link to the AP, the NOMA scheme is generally more preferred in terms of the total throughput.

### B. Evaluation

In this subsection, we evaluate the average system performance over channel fading. In particular, we have the following setup on the channel fading: (A) for the AP-UAV channel with LoS, we apply Rician fading with non-centrality parameter as 1; (B) for the UAV-GU channel, we apply Rician fading with non-centrality parameter as the probability of LoS; (C) finally we apply Rayleigh fading model for the AP-GU channel without LoS.

1) **User Selection:** Fig. 9 illustrates the impact of the GU’s distance (to the AP) on the UAV throughput performance. Note that the NOMA scheme never works at \( \beta > 1 \). Hence, we set the minimum rate coefficient \( \beta = 0.95 \), and evaluate the performance of the NOMA and relaying schemes in both the IBL and FBL regimes. The results are consistent with Fig. 6 and Fig. 8 in that the NOMA scheme is more preferred when the GU is close to the AP. Moreover, Fig. 9 also confirms the results observed in Fig. 6 to Fig. 8 that in the FBL regime relaying provides a relatively higher throughput to UAV than in the IBL regime.

2) **The Impact of FBL Regime in Resource Allocation:** In the following, we investigate how the optimization problem in the FBL regime differs from that in the IBL regime, and what the performance loss is if we directly apply the allocation parameters obtained in the IBL regime into practice. It should be pointed out that the optimal allocation parameter of the NOMA scheme in the IBL regime is not feasible in the FBL regime. It is due to the fact that the power \( p_2 \) obtained in the IBL regime is not able to guarantee the GU’s reliability and throughput requirement in the FBL regime. Therefore, we only compare the IBL throughput with the FBL throughput under the relaying scheme. In particular, three types of results are provided: (A) IBL throughput: the optimal throughput of UAV purely according to the design in the IBL mode; (B) FBL throughput: the optimal throughput of UAV based on the proposed design in the FBL regime; (C) FBL throughput with IBL blocklength: we obtain the optimal blocklength solution in the IBL regime (i.e., using the IBL throughput metrics), and calculate the FBL performance based on these blocklength (BL) results (where the transmit power is reallocated to satisfy the GU’s reliability and throughput requirements).

The impact of the frame length \( M \) on the optimal throughput of the UAV is shown in Fig. 10. Significant performance difference between the designs in the two regimes are observed clearly from the figure. On the one hand, the FBL throughput of UAV is much higher than the IBL throughput, i.e., the IBL
model is inaccurate when the frame length $M$ is relatively short. On the other hand, directly applying the IBL optimal solution to a system operating with FBL codes also introduces considerable performance loss, i.e., the gap between the FBL throughput and FBL throughput with IBL BL (i.e., using the BL results obtained by considering the IBL throughput characterizations).

Moreover, we study the GU’s reliability requirement on the UAV throughput in Fig. 11. Again, significant performance gaps are observed between the FBL and IBL regimes, which confirms that it is necessary and essential to provide the FBL design (under relaying scheme) for a UAV network operating with short blocklengths. Moreover, this necessity is more obvious when the GU has a stringent reliability constraint, i.e., the performance gaps between the curves are more considerable when the GU’s error probability constraint becomes lower.

Finally, although the designs (for optimal resource allocations for a UAV-GU pair under relaying and NOMA schemes) in this work are motivated by utilizing the more favorable channel conditions (with a high probability of LoS) in links from/to the UAV and utilizing the channel quality difference between the AP-UAV and AP-GU links, it should be pointed out that these designs can be also applied for the scenario with a pair of GUs. In the following, we compare these two types of user pairs, i.e., UAV-GU and GU-GU, to show how our designs benefit the UAV connected scenario. We set the locations of the AP and the first (primary) GU to $(0, 0, 20)$ and $(800, 0, 0)$, respectively. In addition, we set the locations of the UAV and the second GU to $(d, 0, 100)$ and $(d, 0, 0)$, i.e., letting the UAV and the second GU have the same ground location/projection, and vary $d$ from 150 m to 1000 m. Moreover, we set the minimum rate coefficient $\beta = 0.95$.

The throughput results of the comparison are provided in Fig. 12. Clearly, owing to the high probability of LoS, the UAV achieves a significantly higher throughput via our designs than the second GU. Moreover, relaying has better performances for both the UAV-GU and GU-GU cases in comparison to NOMA.

The corresponding outage probability results are shown in Fig. 13 where the outage probability represents the probability that the first (primary) GU’s transmission quality cannot be guaranteed, i.e., the probability that the UAV or the second GU cannot be additionally serviced by the AP. It can be observed that the outage probability of the second GU is significantly higher than that of the UAV. In particular, in order to guarantee the first GU’s transmission quality, the GU-GU pair is not able to provide a reliable connection for the second GU when this GU is a relatively far from the AP, e.g., when the distance of the second GU to the AP is longer than 600, the outage probability of the second GU becomes higher than $10^{-1}$. On the other hand, the UAV-GU pair introduces a relatively reliable connection to the UAV. Surprisingly, the NOMA scheme is more reliable for the UAV connection than relaying, which is totally different from the results in Fig. 12 with respect to the throughput. In particular, this performance advantage of NOMA with respect to outage probability is more significant when the UAV is close to the AP.

Combining the results in Fig. 12 and Fig. 13, we conclude that the NOMA scheme has a higher probability to provide a
connection to the UAV, while this connection generally results in a lower throughput to the UAV than the relaying scheme. Hence, the NOMA scheme is more suitable for the data traffic with small data packet sizes and requiring a high probability of connection. Moreover, a hybrid scheme, which dynamically shifts between NOMA and relaying schemes, is strongly suggested for the considered UAV-connected ground network. This hybrid scheme definitely achieves better throughput and outage probability performances than the pure NOMA and relaying schemes, which is more important for UAVs with low-latency high reliability applications.

VII. CONCLUSION

In this paper, we have studied a ground wireless network supporting UAV transmissions, and considered NOMA and relaying schemes. The throughputs of UAV and GU are characterized in the IBL regime and the FBL regime, respectively. Following the throughput characterizations, we have provided optimal resource allocation designs for the NOMA and relaying schemes in both the IBL and FBL regimes. In particular, the objective of the designs is to maximize the UAV throughput while guaranteeing the GU’s transmission quality with respect to throughput and reliability.

Via simulations, we have validated our analytical model and evaluated the system performance. In particular, the results suggest that the NOMA scheme is more preferred if the GU has a good link to the AP (e.g., GU is within a short distance to the AP), while the relaying scheme demonstrates its advantage when the GU is relatively far from the AP. Moreover, the relaying scheme is able to create a win-win situation, i.e., improve the performance of the GU while additionally providing a transmission service to the UAV. More importantly and surprisingly, we have observed that the relaying scheme offers a higher throughput to the UAV in the FBL regime than in the IBL regime, due to the fact that in the FBL regime less resources are required to guarantee the GU’s transmission quality and therefore the extra resources can be allocated to the transmission to the UAV. However, it is also observed that (in comparison to relaying) the NOMA scheme provides a higher UAV throughput by slightly sacrificing the GU’s performance and is more reliable in providing a connection to the UAV than relaying with respect to the outage probability. Hence, a hybrid scheme, which dynamically shifts between NOMA and relaying schemes, is strongly advocated to achieve a high throughput while having a lower outage probability.
