Abstract

The velocity distribution of inelastic granular gas is examined numerically on two dimensional hard disk system in nearly elastic regime using molecular dynamical simulations. The system is prepared initially in the equilibrium state with the Maxwell-Boltzmann distribution, then after a several inelastic collisions per particle, the system falls in the state that the Boltzmann equation predicts with the stationary form of velocity distribution. It turns out, however, that due to the velocity correlation the form of the distribution function does not stay time-independent, but is gradually returning to the Maxwellian immediately after the initial transient till the clustering instability sets in. It shows that, even in the homogeneous cooling state, the velocity correlation in the inelastic system invalidates the assumption of molecular chaos and the prediction by the Boltzmann equation fails.

Free cooling of granular gas under no gravity has been attracting much interest as a subject of statistical mechanics since people realized that the inelastic collisions between particles makes the system behave very different from the elastic system, that is the subject of the conventional statistical mechanics.

Besides the cooling, or loosing its kinetic energy due to the inelasticity, it has been well recognized by now the system shows series of instabilities however small the inelasticity may be as long as the system is large enough. If the system is prepared in a highly agitated state, initially it cools down uniformly as

\[ T = \frac{T_0}{(1 + t/t_0)^{\frac{1}{\gamma}}}, \]

which is called Haff state \[\text{(1)}\]. After a while, the vortex structure develop in the velocity field (the shearing instability) \[\text{(2)}\]; then the uniformity of the particle density is broken (the clustering instability) \[\text{(3)}\].

After the clustering instability, the clusters of particles collide with each other, merge, and split in a complex way \[\text{(4)}\]; the system eventually develops high density region, where the inelastic collapse \[\text{(5, 6)}\] is likely to happen if one consider ideal hard sphere system with a constant restitution coefficient.

Regarding the velocity distribution, the Maxwell-Boltzmann distribution is an equilibrium velocity distribution for the elastic system, and the relaxation to the distribution is known to be very fast, i.e. within a several collisions per particles when it is spatially uniform. In the case of the inelastic system, obviously any velocity distribution cannot be stationary because the system loses kinetic energy at every collision, but it is plausible that the form of distribution stays stationary after a short transient if the velocity is scaled by the average speed \(v_0(t)\):

\[ f(v, t) = \frac{1}{v_0(t)^d} \hat{f} \left( \frac{v}{v_0(t)} \right). \]

In fact, kinetic theories based on the Boltzmann equation predicts that, after a several collisions per particle, the velocity distribution for the inelastic system falls into a stationary form that is different from Gaussian \[\text{(7, 8, 9)}\].

In this report, I present results of large scale two dimensional MD simulations and shows that the form of the velocity distribution does not stay stationary in the inelastic gas, but after a short initial transient the distribution gradually getting back to the Gaussian till
the clustering instability sets in. This gradual change starts at very early stage where the inhomogeneity in the system is hardly visible.

The system we examine is the two dimensional system of hard disks that undergo inelastic collisions with a constant normal restitution $r$. The rotational motion is ignored. Then, the collision rule is given by

$$
\begin{align*}
\mathbf{v}'_i &= \mathbf{v}_i - \frac{1 + r}{2} \left( \mathbf{n} \cdot (\mathbf{v}_i - \mathbf{v}_j) \right) \mathbf{n} \\
\mathbf{v}'_j &= \mathbf{v}_j + \frac{1 + r}{2} \left( \mathbf{n} \cdot (\mathbf{v}_i - \mathbf{v}_j) \right) \mathbf{n},
\end{align*}
$$

where $\mathbf{v}_i$ and $\mathbf{v}'_i$ are the velocity of the $i$'th disk before and after the collision with the $j$'th particle, respectively, and $\mathbf{n}$ is the unit vector parallel with the relative position of the colliding particles at the time of contact.

The average speed $v_0(t)$ for $d$-dimensional system, defined by

$$
\frac{d}{2} v_0(t)^2 = \int d\mathbf{v} f(\mathbf{v}, t) \mathbf{v}^2,
$$

decreases as the system loses energy; with this speed we scale the velocity distribution through eq.(2). In order to see the time-dependence of the scaled velocity distribution $\hat{f}$, it is convenient to expand it using the Sonine polynomial as

$$
\hat{f}(c, t) = \frac{1}{\sqrt{\pi^d}} e^{-c^2} \sum_{\ell=0}^{\infty} a_\ell(t) S_\ell(c^2)
$$

when the distribution is not very different from Gaussian; the $\ell$'th order Sonine polynomial is the $\ell$'th order polynomial orthogonalized with the $d$-dimensional Gaussian weight function:

$$
S_0(x) = 1, S_1(x) = -x + \frac{1}{2} d,
$$

$$
S_2(x) = -\frac{1}{2} x^2 - \frac{1}{2} (d + 2) x + \frac{1}{8} d(d + 2), \text{ etc.}
$$

Due to the normalization and scaling of $\hat{f}$, we have $a_0 = 1$ and $a_1 = 0$, thus any deviation from Gaussian distribution is seen in the non-zero values of $a_\ell$ for $\ell \geq 2$.

Simulations were performed by the event-driven method using the fast algorithm developed by Isobe [10]. Most of the simulations were done with particle number $N = 250,000$, number density $n = 0.25$ (area fraction $\phi \equiv \pi n/4 = 0.196$). I employed the periodic boundary condition and the initial state is the equilibrium state that is prepared by running the
system for long enough with the restitution constant $r = 1$. We focus on the nearly elastic regime where the system stays uniform for a substantial length of time and the distribution does not deviate very much from the Gaussian when the system is in HCS.

In the following, the time is measured by the collision time $\tau$, which is defined as the number of collisions each particle experiences, i.e. $\tau \equiv 2N_{\text{coll}}/N$ with $N_{\text{coll}}$ being the total number of collisions (the factor 2 comes from the binary collision).

Figure 1 shows the energy decay as a function of time $\tau$ for $r = 0.9$ and $n = 0.25$ in the semi-logarithmic scale. In terms of $\tau$, the decay in the Haff state given by (1) is expressed as

$$E(\tau) = E(0) \exp[-\gamma \tau],$$

(5)

where $\gamma$ is a decay rate. The thin solid line in Fig.1 shows the exponential function with $\gamma = 0.093$ (the line is shifted vertically to avoid complete overlapping). The initial $\tau$-dependence fits to the exponential decay very well with the decay rate very close to the one obtained in the case of random collision: $\gamma_0 \equiv (1 - r^2)/d = 0.095$ for $r = 0.9$. It eventually deviates from the exponential around $\tau \sim 70$, when the clustering instability sets in.

The speed distribution for this system is plotted in Fig.2 for $\tau = 40$ and 80. For both cases, the distribution is very close to Gaussian and the deviation from it is hardly seen.

The deviation, however, is clearly seen in $a_2(\tau)$ plotted in Fig.3, where the initial deviation from the Gaussian is shown for various values of restitution constant $r$. From this figure, it might seem that the scaled distribution becomes stationary after a several collisions per particle as is expected from the kinetic theories [7, 8, 9]. These “stationary” values of $a_2$ agree very well with the results of kinetic theory for the nearly elastic region $r \geq 0.95$ (Fig.4).

This form of distribution, however, is not really stationary as it may look in the initial stage data of Fig.3. The $\tau$ dependence of Sonine coefficients over longer time scale is shown in Fig.5 for $r = 0.9$, 0.95, and 0.98. In this time scale, the plateau is hardly seen and absolute value of all the coefficient show gradual decrease towards zero till the time when the clustering instability sets in; after that time the distribution deviates from Gaussian drastically.

The Sonine coefficient $a_2(\tau)$ for various $r$ is plotted in Fig.6 where the time is scaled by the clustering time $\tau^*$ when the clustering instability sets in and $a_2$ is scaled by its maximum absolute value $|a_2^*|$ for each $r$. The closer the value of $r$ is to 1, the smaller the
slope in the $\tau$ dependence becomes, but for all cases, the gradual return to Gaussian starts almost immediately after the initial transient period finishes. It starts actually far before any instability becomes evident.

This behavior obviously contradicts to the results of the kinetic theories based on the Boltzmann equation [7, 8, 9]; the theories predict the distribution shows the stationary form after the short initial transient. The stationary form should last till the Boltzmann equation becomes invalid due to correlations developed in the system. The fact that the distribution function starts to deviate from the stationary form quite early stage suggests that the correlation due to inelasticity becomes important much earlier than it is generally expected [11].

The correlation that is responsible to the behavior of the velocity distribution is the velocity correlation. This can be seen by examining the behavior of the system where the particle velocity is artificially randomized by the operation that the velocity of each particle is shuffled by exchanging them between pairs chosen randomly. By doing this, we destroy the spatial correlation of velocity while preserving the velocity distribution. The dashed line in Fig.1 shows the energy decay with the velocity shuffling and indicates that the clustering is prevented by the velocity shuffle. From Fig.7, we can see clearly that this system shows the stationary form of the velocity distribution whose Sonine coefficients are closer to those predicted by the theories.

In Fig.7, the density dependence of the Sonine coefficient behavior is also examined for $n = 0.25, 0.111$, and $0.0625$. The general tendency that $|a_2|$ decreases toward zero after the initial deviation is the same and they are all clearly different from the case with the velocity shuffling although a certain density dependence exists in the present density region [12].

The kinetic theories have succeeded in explaining many aspects of granular gas, but the Boltzmann-Enskog equation, on which most of the theories based, ignores the particle correlations except for the pair correlation factor of the position. This approximation is quite good in the equilibrium system thanks to the absence of the velocity correlation. In the inelastic systems, however, the system develops the velocity correlation, and the assumption of molecular chaos fails even at very early stage, where the system is still in HCS. This invalidates the prediction based on the Boltzmann equation that the functional form of the velocity distribution of the inelastic system in HCS becomes stationary.

In summary, using large scale MD simulations, I have demonstrated that in the inelastic
system the velocity distribution does not stay in a stationary form, contrary to the expectation by the kinetic theories based on the Boltzmann equation. This is due to the velocity correlation developed through the inelastic collisions, and this effect manifests itself in the velocity distribution from very early stage where any instabilities caused by the inelasticity are still hardly visible.

[12] The behavior after the clustering($\tau \geq 70$) shows strong sample dependence for the present system size ($N = 250,000$) while the behavior in the homogeneous state is quite stable.
FIG. 1: Energy decay as a function of $\tau$ for $r = 0.9$ and $n = 1/4$. The solid line denotes the result for the system with the ordinary inelastic dynamics and the dashed line for the system with the velocity shuffle (see the text). The exponential decay (5) with $\gamma = 0.093$ is also plotted by the thin solid line with an extra factor to avoid complete overlapping with the dashed line.

FIG. 2: The scaled speed distributions for $\tau = 40$ and 80 with $r = 0.9$ and $n = 1/4$. The plot for $\tau = 80$ is shifted by the factor $10^{-1}$. The Maxwell-Boltzmann distributions are indicated by the solid lines for comparison.
FIG. 3: The initial time dependence of $a_2$ for $r = 0.99$ (top), 0.98, 0.95, and 0.90 (bottom) with $n = 1/4$. 
FIG. 4: The Sonine coefficients $a_\ell \ (2 \geq \ell \geq 5)$ for $r = 0.9$ (top), 0.95 (middle), and 0.98 (bottom) as functions of $\tau$ for $n = 1/4$. 
FIG. 5: The scaled Sonine coefficient $a_2/|a_2^*|$ v.s. the scaled time $\tau/\tau^*$ for $r = 0.90, 0.95, 0.98,$ and 0.99 with $n = 1/4$.

FIG. 6: The minimum values for $a_2$ v.s. the restitution constant $r$. The solid line indicates the results by the Boltzmann equation [3].
FIG. 7: The Sonine coefficient $a_2$ for $r = 0.9$ as a function of $\tau$ for the ordinary dynamics (solid line) and the velocity shuffled dynamics (dashed line) for $n = 1/4$. $a_2$ for $n = 0.1111$ (the dash-dotted line) and $n = 0.0625$ (the dotted line) with the ordinary dynamics are also plotted.
