ABSTRACT

Recent long-wavelength observations on the thermal dust continuum suggest that the Rayleigh–Jeans tail can be used as a time-efficient quantitative probe of the dust and interstellar medium (ISM) mass in high-$z$ galaxies. We use high-resolution cosmological simulations from the Feedback in Realistic Environment (FIRE) project to analyse the dust emission of $M_* \gtrsim 10^{10} M_{\odot}$ galaxies at $z = 2-4$. Our simulations (MassiveFIRE) explicitly include various forms of stellar feedback, and they produce the stellar masses and star formation rates of high-$z$ galaxies in agreement with observations. Using radiative transfer modelling, we show that sub-millimetre (sub-mm) luminosity and molecular ISM mass are tightly correlated and that the overall normalization is in quantitative agreement with observations. Notably, sub-mm luminosity traces molecular ISM mass even during starburst episodes as dust mass and mass-weighted temperature evolve only moderately between $z = 4$ and $z = 2$, including during starbursts. Our finding supports the empirical approach of using broadband sub-mm flux as a proxy for molecular gas content in high-$z$ galaxies. We thus expect single-band sub-mm observations with ALMA to dramatically increase the sample size of high-$z$ galaxies with reliable ISM masses in the near future.

Key words: galaxies: evolution – galaxies: high-redshift – galaxies: ISM – submillimetre: galaxies.

1 INTRODUCTION

Molecular gas is a key component of the interstellar medium (ISM) affecting the physics of galaxy and star formation. Measuring the molecular gas mass in galaxies in different environments and at various evolutionary stages provides important constraints to the nature of the relevant physical processes, such as gas heating and cooling, turbulence, and feedback (see e.g. Klessen & Glover 2016, and references therein). It is also essential for understanding a wide variety of observational properties and the scaling relationships of galaxies (e.g. Noeske et al. 2007; Tacconi et al. 2010; Scoville et al. 2017).

Unfortunately, observing cold molecular hydrogen is extremely difficult, and CO rotational transition lines have widely been used to probe molecular ISM masses. While CO detections provide a handle on the physical state of the ISM, this method is time-intensive, and for high-$z$ galaxies, the bulk of the observations are limited to high-$J$ transitions. The conversion from a high-$J$ line intensity to a molecular ISM mass depends on the density and temperature of the CO-emitting gas, and could vary at the order of magnitude level between individual galaxies (see e.g. Shetty et al. 2011; Feldmann, Gnedin & Kravtsov 2012; Carilli & Walter 2013; Narayanan & Krumholz 2014; Olsen et al. 2016; Richings & Schaye 2016).

To overcome such disadvantages, there have been emerging efforts to use alternative probes of the ISM mass in massive high-$z$ galaxies, such as the CI line emission (e.g. Oppen et al. 2014; Andreani et al. 2018) and the long-wavelength dust thermal emission (e.g. Magdis et al. 2012; Scoville et al. 2014, 2016; Hughes et al. 2017; Scoville et al. 2017; Harrington et al. 2018). In particular, measuring ISM masses based on single-band sub-mm/mm fluxes from the dust emission offers the prospect of efficiently generating large samples of high-$z$ galaxies with estimated ISM masses.

Recently, Scoville et al. (2016, hereafter S16) carried out an empirical calibration between the rest-frame specific luminosity at 850 μm ($L_{850\mu m}$) and the CO-derived (via $J = 1 \to 0$) molecular ISM mass ($M_{\text{mol}}$) using a compiled sample of local star-forming...
spirals, ultraluminous infrared galaxies (ULIRGs), and high-z submillimetre galaxies (SMGs)). They find that the \( L_{850\mu m}/M_{\text{mol}} \) ratio of the galaxies in that sample is nearly constant with \( L_{850\mu m} \) suggesting that the flux density in the Rayleigh–Jeans (RJ) tail could be used as a proxy for \( M_{\text{mol}} \), given the distance to the object.

Estimating the reliability of this approach is of paramount importance if sub-mm observations are to be used to infer physical properties of the baryonic cycle in high-redshift galaxies. One potential caveat with the high-z data set of S16 is that it is limited to bright (\( S_{850\mu m} \gtrsim 1 \text{ mJy} \)) sources. It is thus unclear whether the \( L_{850\mu m}/M_{\text{mol}} \) ratio applies to sub-mJy sources at high-z that are observable with ALMA thanks to its high sensitivity and resolution (e.g. Ono et al. 2014; Aravena et al. 2016). Furthermore, the molecular ISM masses in S16 are derived from CO line observations and are thus susceptible to various systematic uncertainties.

To assess the robustness of the sub-mm technique for estimating molecular ISM masses, we study the \( M_{\text{mol}}/L_{850\mu m} \) conversion factor, \( \alpha_{850} \), in massive (\( M_* \gtrsim 10^{10} \text{ M}_\odot \)) high-z (\( z = 2-4 \)) galaxies drawn from a suite of cosmological zoom-in simulations (MASSIVEFIRE; Feldmann et al. 2016, 2017) that are part of the Feedback In Realistic Environments (FIRE) project (Hopkins et al. 2014).

A number of previous studies have greatly improved our understanding of the nature of the sub-mm sources, as well as how various galactic properties impact the sub-mm flux (e.g. Narayanan et al. 2010a; Hayward et al. 2011, 2013; Narayanan et al. 2015). However, to our knowledge, there has not yet been any theoretical study that probes \( \alpha_{850} \) with the help of 3D radiative transfer (RT) in a self-consistent cosmological setting. In addition, this work improves on previous theoretical studies by increasing the numerical resolution and by modelling star formation and stellar feedback more realistically in a galactic context.

This letter is organized as follows: In Section 2, we present the simulation details and methodology of our analysis. We investigate the \( \alpha_{850} \) conversion factor in Section 3. We discuss caveats and conclude in Section 4. Throughout this letter, we adopt cosmological parameters in agreement with the 9-yr data from the Wilkinson Microwave Anisotropy Probe (Hinshaw et al. 2013), specifically \( \Omega_m = 0.2821 \), \( \Omega_{\Lambda} = 0.7179 \), and \( H_0 = 69.7 \text{ km s}^{-1} \text{ Mpc}^{-1} \).

2 SIMULATION AND ANALYSIS METHODOLOGY

We extract our galaxy sample from the MASSIVEFIRE cosmological zoom-in suite (Feldmann et al. 2016, 2017), which implements all the same FIRE physics and numerical methods as other FIRE-1 simulations (Hopkins et al. 2014). We include 18 massive (\( 10^{10} < M_* < 10^{11.5} \text{ M}_\odot \)) at \( z = 2 \) central galaxies (from the Series A, B, and C in Feldmann et al. 2017) and their most massive progenitors (MMPs), identified using the Amiga Halo Finder (AHF) (Gill, Knebe & Gibson 2004; Knollmann & Knebe 2009). These galaxies reside in a variety of environmental overdensities and have a range of accretion histories. Masses and minimum adaptive gravitational softening lengths of individual gas (dark matter) particles are \( 3.3 \times 10^4 \text{ M}_\odot \) (\( 1.7 \times 10^4 \text{ M}_\odot \)) and \( \epsilon_s = 9 \) (143) proper pc, respectively. FIRE simulations account explicitly for stellar feedback and the multiphase (molecular through hot) ISM (Hopkins et al. 2014).

We produce the UV-to-mm continuous SEDs for our MASSIVEFIRE sample from multiple viewing angles with the publicly available 3D Monte Carlo RT code skirr3 (Baes et al. 2011; Camps & Baes 2015), using the methodology of Camps et al. (2016) (see also Trayford et al. 2017) except for the (here unnecessary) particle re-sampling. In brief, stars older than 10 Myr are assigned tabulated SEDs according to their age and metallicity while younger stars are assigned source SEDs (Groves et al. 2008). The PDR covering fraction is set to \( f_{\text{pdr}} = 0.2 \) (Groves et al. 2008; Jonsson, Groves & Cox 2010). Dust associated with unresolved birthclouds of young star clusters is removed from their neighbouring gas particles to avoid double-counting.

3 THE RESULTS

3.1 The sub-mm-to-CO scaling relation

The S16 compilation includes 28 local star-forming spiral galaxies, 12 ULIRGs, and 30 \( z = 1.5-3 \) SMGs, with galaxy-integrated sub-mm dust emission and molecular ISM masses. S16 convert the

3skirr accounts for the scattering, absorption, and emission by dust, and calculates the dust temperature iteratively until convergence, see www.SKIRT.ugent.be.
Submillimetre flux as a probe of molecular ISM mass

Figure 1. Ratio of $L_{850 \mu m}$ to $M_{mol}$, i.e. $\alpha_{850}$, as function of $L_{850 \mu m}$. Filled symbols represent the result of MassiveFIRE galaxies at $z = 2$ (triangles), $z = 3$ (squares), and $z = 4$ (circles), while empty symbols show the compilation of the recent observations from S16. Empty triangles, diamonds, and inverse triangles represent SMGs, ULIRGs, and local spirals, respectively. $L_{850 \mu m}$ of SMGs are de-lensed by the previously reported magnification factor $\mu$. Grey lines show a linear fit to the S16 data. Dashed and solid line show results obtained using original and de-lensed $L_{850 \mu m}$ of SMGs. Simulated galaxies are coloured according to their dust-to-(molecular) gas mass ratio, $\delta_{dgr}$, indicating a weak trend of $\alpha_{850}$ on $\delta_{dgr}$. MassiveFIRE simulations predict $\alpha_{850}$ values in good agreement with those of star forming and sub-mm galaxies at $z \approx 2$.

The most luminous galaxy in our sample at $z = 2$ has $S_{850 \mu m} \approx 1.5$ mJy ($L_{850 \mu m} \approx 4.5 \times 10^{30}$ erg s$^{-1}$ Hz$^{-1}$), which overlaps with (the fainter end of) observed $z \approx 2$ SMGs. This galaxy is massive ($M_\star \sim 1.5 \times 10^{11}$ $M_\odot$) within 0.1 $R_\text{vir}$ excluding satellites) and undergoing multiple mergers at $z \approx 2$. The stellar mass and 20-Myr-averaged SFR within the SCUBA beam size centred on the galaxy are $\sim 5 \times 10^{10} M_\odot$ and $\sim 350 M_\odot$ yr$^{-1}$. The conversion factor of this galaxy ($\alpha_{850} \sim 5 \times 10^{19}$ erg s$^{-1}$ Hz$^{-1}$ $M_\odot$)$^{-1}$) is in good agreement with S16. The mass-weighted dust temperature of this system is roughly 27 K (as is shown in Fig. 2), similar to the dust temperature $T_{dust} = 25$ K adopted by S16.

The sample also contains 12 (9) candidates of faint SMGs at $z = 2$ ($z = 3$) with $S_{850 \mu m} \gtrsim 0.1$ mJy. One $z = 4$ galaxy in our sample has $S_{1.3 mm} \gtrsim 0.1$ mJy ($z \approx 4$ objects are often measured at longer wavelength to ensure that the observed sub-mm fluxes originate from the optically-thin RJ tail). The fainter $z = 2$ MassiveFIRE galaxies are in good agreement with the linear scaling by S16, derived using local and high-$z$ samples. This suggests that the 850 $\mu m$ flux may be a reliable proxy for the molecular ISM mass of high-$z$ faint SMGs.

The data also reveal that $\alpha_{850}$ depends on the dust-to-(molecular) gas mass ratio, $\delta_{dgr}$. Specifically, more dust-rich galaxies tend to have higher $\alpha_{850}$. As a consequence, $\alpha_{850}$ increases by about 0.08 dex between $z = 4$ to $z = 2$ for the galaxies in our sample, mirroring their metal and dust enrichment.

We can understand the behaviour of $\alpha_{850}$ qualitatively with the help of a single-temperature dust model. For such a model, the flux density in the RJ tail scales as $\propto M_{dust}T_{dust}$ (Casey, Narayanan & Cooray 2014). In Fig. 2, we show the scaling relationship between $M_{dust}T_{dust}$ and $L_{850 \mu m}$ for the MassiveFIRE galaxies, where $M_{dust}$ is the mass of the dust in the diffuse ISM and $T_{dust}$ represents its mass-weighted temperature. It can be seen that $L_{850 \mu m}$ is tightly correlated with $M_{dust}T_{dust}$ of the simulated galaxies, and therefore

$$\alpha_{850} = \frac{L_{850 \mu m}}{M_{mol}} \propto \left( \frac{M_{dust}}{M_{mol}} \right) T_{dust} = \delta_{dgr} T_{dust}. \quad (1)$$

At $z = 2$, our simulated galaxies have an approximately constant $\alpha_{850}$ due to their similar dust-to-gas mass ratios ($\delta_{dgr} \approx 1/125$) and dust temperatures ($T_{dust} \approx 23$ K). The gentle increase of $T_{dust}$ with $L_{850 \mu m}$ seen in Fig. 2 explains the minor increase of $\alpha_{850}$ with increasing $L_{850 \mu m}$ at fixed $\delta_{dgr}$ seen in Fig. 1.

When using ‘derived’ $L_{850 \mu m}$ (see below) instead of actual 850 $\mu m$ rest-frame luminosities, we find a weak correlation between $\alpha_{850}$ and $L_{850 \mu m}$ with slope $0.10 \pm 0.06$ for the full $z = 2$ sample in good agreement with the empirical findings of S16. Derived 850 $\mu m$ luminosities are computed based on $S_{850 \mu m}$ by convolving the redshifted SED with the transmission function of the SCUBA-2 850 $\mu m$ filter (Holland et al. 2013). The derived $L_{850 \mu m}$ is higher (lower) than the actual value for galaxies with $T_{dust}$ higher (lower) than 25 K, as shown in Fig. 2.

Combining the data for all simulated galaxies with $S_{850 \mu m} \gtrsim 0.1$ mJy (for $z = 2$ and $z = 3$) and $S_{1.3 mm} \gtrsim 0.1$ mJy (for $z = 4$),

Figure 2. $M_{dust}T_{dust}$ against $L_{850 \mu m}$, where $M_{dust}$ and $T_{dust}$ represent the total mass and the mass-weighted temperature of the diffuse ISM dust. Triangles, squares, and circles represent the MassiveFIRE galaxies at $z = 2$, $z = 3$, and $z = 4$, respectively. For $z = 2$, filled symbols show the actual $L_{850 \mu m}$, while empty symbols show $L_{850 \mu m}$ derived from $S_{850 \mu m}$ as in S16 with $T_{dust} = 25$ K. The diagonal line marks the linear scaling $M_{dust}T_{dust} = 2.8 \times 10^{-21} L_{850 \mu m}M_\odot$ K Hz erg$^{-1}$. Data are coloured by $T_{dust}$. The 850 $\mu m$ luminosity is proportional to the dust mass and the mass-weighted temperature of the diffuse ISM dust.

The sample contains 12 (9) candidates of faint SMGs at $z = 2$ ($z = 3$) with $S_{850 \mu m} \gtrsim 0.1$ mJy. One $z = 4$ galaxy in our sample has $S_{1.3 mm} \gtrsim 0.1$ mJy ($z \approx 4$ objects are often measured at longer wavelength to ensure that the observed sub-mm fluxes originate from the optically-thin RJ tail). The fainter $z = 2$ MassiveFIRE galaxies are in good agreement with the linear scaling by S16, derived using local and high-$z$ samples. This suggests that the 850 $\mu m$ flux may be a reliable proxy for the molecular ISM mass of high-$z$ faint SMGs.
respectively, we obtain the following scaling relation for the conversion factor between molecular ISM mass and rest-frame 850 μm flux density

\[
\alpha_{850}^{-1} = 10^{19.71 \pm 0.02} \left( \frac{\delta_{dgr}}{0.01} \right)^{0.53 \pm 0.07} \left( \frac{L_{850 \mu m}}{10^{11} \text{ erg s}^{-1} \text{ Hz}^{-1}} \right)^{0.06 \pm 0.04} \text{ erg s}^{-1} \text{ Hz}^{-1} \text{ M}_\odot^{-1}. \tag{2}
\]

The sub-unity of the scaling between \(\alpha_{850}\) and \(\delta_{dgr}\) results from a (non-trivial) anticorrelation between \(T_{\text{dust}}\) and \(\delta_{dgr}\) (see also e.g. Safarzadeh et al. 2016).

The scatter of the simulated \(z = 2\) data (0.09 dex) is smaller than that of the observed SMG sample (0.24 dex). The higher scatter in the observational data may arise from uncertainties in the CO (1−0) to \(M_{\text{mol}}\) conversion, which is known to depend on the ISM conditions of individual galaxies, including gas metallicity and internal UV radiation field (e.g. Feldmann, Gnedin & Kravtsov 2012; Genzel et al. 2012; Bolatto, Wolfire & Leroy 2013; Richings & Schaye 2013). Additionally, our simulations likely underestimate the scatter as they assume a fixed dust-to-metal ratio.

The PDR covering fraction, \(f_{\text{pdr}}\), appears to have little impact on \(\alpha_{850}\) if high-z star-forming regions are in a compact configuration (high \(C\)). Using \(f_{\text{pdr}} = 1\) (\(f_{\text{pdr}} = 0\)), increases (decreases) \(\alpha_{850}\) by \(\sim 10\) percent (1 percent). Furthermore, \(L_{850 \mu m}/M_{\text{mol}}\) does not vary significantly with the orientation of the galaxy because the long-wavelength dust continuum is optically thin.

### 3.2 The temporal evolution of sub-mm luminosity

In the previous section, we studied the sub-mm luminosity and its relation to molecular ISM mass at fixed redshifts. We now investigate how the sub-mm luminosity of our simulated galaxies varies with time, especially during starburst (SB) episodes.

To this end, we track each galaxy back in time via their MMFs until \(z = 4\). For each galaxy we compute \(L_{850 \mu m}\) and calculate the total infrared luminosity, \(L_{\text{IR}}\) (over \(\lambda_{\text{rest}} = 8−1000 \mu m\)), using the output SED from our model. We also calculate the molecular ISM mass, 20-Myr-averaged SFR, and total gas mass. As a representative example, we show in Fig. 3 the temporal evolution of the various properties for the \(L_{850 \mu m}\)-brightest MassiveFIRE galaxy.

This galaxy has several starbursting and quiescent phases on time-scales of \(\sim 100\) Myr. SBs are sometimes but not always associated with galaxy mergers in MassiveFIRE simulations (Feldmann et al. 2017; Sparre et al. 2017). In most cases, SBs coincide with periods of increased gas density and molecular ISM mass. During an SB, molecular gas is quickly consumed by star formation, which subsequently drives gas away from the star-forming region by stellar feedback (Muratov et al. 2015) temporarily reducing SFRs (Feldmann et al. 2017).

The figure demonstrates that \(L_{\text{IR}}\) is well correlated with the SFR. This is expected as \(L_{\text{IR}}\) traces the energy absorbed by the dense dust in vicinity of the young star clusters from their UV radiation, and is thus commonly used as an indicator of (obscured) star formation (e.g. Kennicutt 1998; Calzetti et al. 2010). \(L_{850 \mu m}\), however, shows less correlation with SFR and instead mirrors the build-up of molecular ISM mass. How do we understand that \(L_{850 \mu m}\) tracks \(M_{\text{mol}}\) much better than \(L_{\text{IR}}\) even during SBs? In our simulations, \(L_{\text{IR}}\) arises largely from the hot dust close to the young star clusters, while \(L_{850 \mu m}\) traces the bulk of the (mostly diffuse) ISM dust. During the SBs, the mass fraction of the dense dust increases as the ISM becomes more compact, yet the total dust mass hardly changes and \(T_{\text{dust}}\) increases only slightly. As \(L_{850 \mu m}\) is well correlated with \(M_{\text{mol}}T_{\text{dust}}\) (as shown in the right subplot of Fig. 3), \(L_{850 \mu m}\) tracks the (smoothly evolving) total dust mass and, consequently, \(M_{\text{mol}}\), while \(L_{\text{IR}}\) tracks the highly variable mass of dense and hot dust.

The reason for the weak evolution of dust temperature is twofold. First, during SB periods, gas and dust near the star-forming regions tend to be more compact resulting in increased absorption of UV radiation from embedded young star clusters. Re-emitted (IR) photons heat the remaining ISM dust inefficiently because of the low dust opacity at infrared wavelength. Secondly, the dust temperature scales only weakly (to the 1/6–1/5 power) with the local radiation density (Casey et al. 2014).

Hence, \(\alpha_{850}\) shows little short-term variance (changes are \(\lesssim 2\times\)) even during SB episodes. Interestingly, modest deviations are sometimes seen during quiescent episodes when low-molecular ISM masses drive temporary increases in \(\alpha_{850}\). Between \(z = 4\) and \(z = 2\), \(\alpha_{850}\) increases by \(\sim 60\) percent due to a growing \(\delta_{dgr}\). In contrast, over the same time frame, dust, and gas masses as well as IR luminosities increase by one order of magnitude.

In summary, we find that 850 μm flux density is a reliable proxy for molecular ISM mass even for starbursting systems.

### 4 SUMMARY AND DISCUSSION

The long-wavelength dust thermal continuum has been used as an alternative to the traditional CO line method for constraining the molecular ISM mass of massive (\(M_* \gtrsim 10^{10} \text{ M}_\odot\)) high-z galaxies. We have coupled MassiveFIRE cosmological-zoom galaxies with dust radiative transfer to generate their UV-to-mm continuum SED. The sample covers two orders of magnitude in \(L_{850 \mu m}\), with the brightest \(z = 2\) galaxy overlapping with the range of the observed SMGs.

The ISM-mass-to-sub-mm-luminosity-ratio, \(\alpha_{850}\), of our simulated sample of galaxies is in good agreement with the SMG sample from the S16 compilation (Fig. 1). Overall, \(\alpha_{850}\) varies little with \(L_{850 \mu m}\). \(\alpha_{850}\) depends primarily on the dust temperature and dust-to-(molecular) gas mass ratio and both quantities are similar among the galaxies in our sample.

When we look in more detail, we see that \(\alpha_{850}\) slightly decreases with decreasing redshift as galaxies become successively more metal and dust-enriched. Specifically, we find \(\alpha_{850} = L_{850 \mu m}/M_{\text{mol}} \propto \delta_{dgr}^{-\frac{1}{2}}\) (equation 2), which explains most of the scatter of \(\alpha_{850}\) in our simulated sample. Indeed, the scatter in \(\alpha_{850}\) at fixed \(\delta_{dgr}\) is small (0.02 dex), showing that \(\alpha_{850}\) largely tracks the dust enrichment in high-redshift galaxies. We therefore suggest the use of a dust-to-gas-ratio-dependent conversion factor to increase the accuracy of the sub-mm-estimated ISM masses. Observers can estimate \(\delta_{dgr}\) using the \(\delta_{dgr}−Z\) scaling (Magdis et al. 2012), and metallicities can be derived from optical (e.g. Kewley & Ellison 2008) and FIR (e.g. Rigopoulou et al. 2018) line emission, or the \(M_*−Z\) relationship (Tremonti et al. 2004; Erb et al. 2006).

In our simulated galaxies, the mass-weighted dust temperatures (\(T_{\text{dust}}\)) evolve relatively little between \(z = 4\) and \(z = 2\), rendering \(\alpha_{850}\) insensitive to the burstiness of star formation.

Our findings thus suggest that single-band sub-mm techniques can reliably constrain the molecular ISM masses of both main-sequence and SB galaxies. Future single-band surveys with ALMA may dramatically increase the sample size of high-z galaxies with
Figure 3. Temporal evolution of the various properties of the $L_{850\mu m}$-brightest MassiveFIRE galaxy from $z = 4$ to $z = 2$. Left: In the top panel, the normalized $M_{\text{mol}}, \text{SFR}, L_{IR}$, and $L_{850\mu m}$ are shown by the blue, black, magenta, and red lines. The middle panel shows the evolution of $L_{850\mu m}/M_{\text{mol}}$ (violet), $T_{\text{dust}}$ (blue), and $\delta_{\text{dgr}}$ (red). The mass of the dense (red line) and diffuse (blue line) dust are shown in the lower middle panel. Starburst and quiescent phases are marked by red and blue shaded blocks. Right: The subplot shows the trajectories of three selected galaxies on the $M_{\text{dust}}$-$T_{\text{dust}}$ versus $L_{850\mu m}$ diagram. The red line corresponds to the $L_{850\mu m}$-brightest galaxy, and black and blue lines show an intermediate and a low-luminosity system. Yellow stars mark the position of these galaxies at $z = 2$. $L_{850\mu m}$ and $M_{\text{mol}}$ co-evolve even during starbursts resulting in a roughly constant $\alpha_{850}$. $L_{IR}$ traces well the SFR.

ACKNOWLEDGEMENTS

We thank the anonymous referee for comments that help improve the quality of this letter. We thank Onur Çağmabacak, Tine Coleman, Nick Gnedin, Kevin Harrington, Claudia Lagos, and Desika Narayanan for valuable discussions. We thank Peter Camps for providing SSP libraries for the STARBURST99 stellar evolution model.
